# PNEUMOTHORAX

DOUGLAS SEATON

A pneumothorax is defined as the presence of air within the pleural cavity. The term was first used in the doctoral thesis of the French physician Itard in 1803 [1], although the presence of abnormal collections of air and fluid within the chest might have been inferred as early as the fifth century BC by physicians in ancient Greece who practised so-called Hippocratic succussion of the chest [2,3].

## Classification and terminology

In health each lung is surrounded by two contiguous layers of pleura separated by the potential space known as the pleural cavity. The pressure in this space is negative with respect to the atmosphere and as a result the elastic structures comprising the lung are held in apposition to the chest wall. Should air gain entry to the pleural cavity by whatever means, intrapleural pressure becomes less negative with respect to atmospheric pressure and this permits the lung to move away from the chest wall by deflation until a point is reached at which the pressure remains sufficiently negative to prevent further collapse. Should the pressure in the pleural cavity reach that of the atmosphere then a complete, as opposed to a partial, pneumothorax is said to exist. Should intrapleural pressure exceed that of the atmosphere then as well as the pneumothorax being complete, the structures comprising the mediastinum are compressed and displaced to the opposite side producing a tension pneumothorax.

From the foregoing it is clear that a pneumothorax cannot occur unless the integrity of either the visceral or parietal layer of pleura, or both, is breached. Should the breach remain patent then a fistula exists and the pneumothorax may be described as open. More frequently the breach seals off, resulting in a closed pneumothorax. A tension pneumothorax arises when the defect is valve-like, permitting air to pass into the pleural cavity on inspiration but preventing its escape. A working classification of pneumothorax based on aetiology is given in Fig. 44.1.

## Spontaneous pneumothorax

Any pneumothorax occurring in the absence of trauma may be described as spontaneous (syn. primary simple pneumothorax, primary pneumothorax, simple pneumothorax, pneumothorax simplex, idiopathic pneumothorax). The term 'primary spontaneous pneumothorax' is used in the absence of clinical evidence of pre-existing respiratory disease, while 'secondary spontaneous pneumothorax' denotes a clinically recognizable coexisting structural or functional abnormality in the lung. In a histopathological sense this distinction is somewhat artificial as small defects in the pleura and adjacent lung (see below) have been causally related to primary spontaneous pneumothorax. However, it should be stressed that the distinction remains clinically valid, since these defects in primary spontaneous pneumothorax are of no functional significance and usually go undetected prior to the event. Some cases of secondary spontaneous pneumothorax may at first be misclassified as primary before the underlying clinical condition evolves to the point of recognition.

## Primary spontaneous pneumothorax

Spontaneous pneumothorax most commonly occurs in apparently healthy subjects with no history of pre-existing lung disease. In a series of 210 consecutive cases of spontaneous pneumothorax admitted to a teaching hospital over a 5-year period, 67% fell into this primary category [4]. Primary spontaneous pneumothorax is predominantly a disease of young adults, being rare in children [5], the peak incidence falling in the third decade [4,6,7]. One study found that spontaneous pneumothorax was primary in 81% of cases presenting at the age of 45 years or under [4]. It is also of note that the condition predominantly affects males, the male to female ratio lying somewhere between the 12:1 found in a study of 118 cases of primary spontaneous pneumothorax [8], 4:1 in a series of 400 cases [9] and 3:1 in a later Swedish community survey that included 2414 patients [10]. In a detailed community-

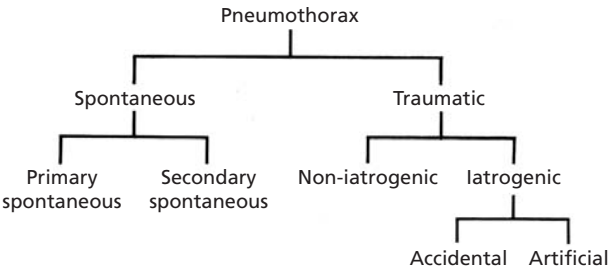

Fig. 44.1 Classification of pneumothorax.

based survey carried out in Minnesota, USA, the incidence of primary spontaneous pneumothorax was found to be 7.4 per 100 000 per year for males and 1.2 per 100 000 per year for females [11]. A similar overall incidence has been reported in the UK [6]. The annual incidence in Stockholm was found to be higher at 18 per 100 000 for men and 6 per 100 000 for women [10]. The right and left lung appear to be affected with equal frequency [12].

**Aetiology** (Table 44.1)

In the early part of the twentieth century spontaneous pneumothorax was, in the minds of most physicians, inextricably bound up with pulmonary tuberculosis, Biach [13] having described such an association in 79% of 918 cases of pneumothorax. A gradual realization that pneumothorax could occur in the absence of underlying lung disease subsequently emerged and Kjaergaard's monograph [14] in which he reviewed 51 cases did much to cause general acceptance of the concept of primary spontaneous pneumothorax. This results from the rupture into the pleural cavity of a small air-filled space know as a pulmonary bleb (Fig. 44.2), a localized collection of air within the cellular layers of the visceral pleura that is contiguous with the lung parenchyma [15]. Blebs may arise as a result of a congenital weakness in the connective tissue of subpleural alveoli and electron microscopic studies have demonstrated that communications exist between blebs and the adjacent alveolar spaces [16]. In cases of primary spontaneous pneumothorax coming to surgery it has been shown that blebs are very common, occurring in over 90% of patients [17], are frequently multiple, occur most commonly at the lung apices and are found in the uncollapsed contralateral lung almost as frequently as in the lung where the pneumothorax has occurred [18,19]. Blebs may occur more frequently at the lung apices as a result of the regional differences in mechanical stresses known to exist within the lungs [20]. In the upright posture a gravity-dependent gradient of negative intrapleural pressure extends along the length of each lung so that distending forces are greatest over the lung apices [21], just as a loosely coiled spring, when suspended by its uppermost coil, becomes progressively more expanded by its own

weight from bottom to top (Fig. 44.3). It has also been suggested that the relative ischaemia at the apex of the lung makes this area more susceptible to infection, so that blebs may develop as a result of inflammation occurring in a zone of maximal stress [22] and there is some histological support for this view [19]. A higher incidence of primary spontaneous pneumothorax has been recorded in individuals who have a tall and thin body habitus. In a study comprising 92 patients with primary spontaneous pneumothorax, mean height was found to be 5 cm greater and mean weight 11 kg less than predicted [23]. A study in the UK recorded a similarly increased mean height in patients with primary spontaneous pneumothorax [24]. In a Japanese study that compared patients with primary spontaneous pneumothorax with controls, those in the pneumothorax group were no taller but had significantly longer lungs and were also leaner [25]. In a detailed epidemiological study in the USA it was concluded that much of the male predominance in spontaneous pneumothorax could be explained in terms of height [11].

There have been several case reports of primary spontaneous pneumothorax occurring in families [26–28]. In one such report an association between spontaneous pneumothorax and specific human leucocyte antigen (HLA) and antitrypsin phenotypes was suggested but not proved conclusively [29]. In a study of 286 Israeli military personnel, a positive family history of primary spontaneous pneumothorax was obtained in 11.5% of cases [30]. The

**Fig. 44.2** (a) Left pneumothorax showing blebs at apex. (b) Operative specimen showing excised blebs.

lungs of some patients with spontaneous pneumothorax have been reported to contain high levels of soluble hydroxyproline. This substance is a degradation product of collagen and the finding was taken to imply an abnormality in the structure or biosynthesis of lung collagen resulting in its increased breakdown [31]. A high incidence of tobacco smoking has been reported in several series of primary spontaneous pneumothorax and this may be a

predisposing factor [7,11,32,33]. A Swedish study found that there was a significant dose-response relationship between smoking and the occurrence of primary spontaneous pneumothorax, the habit increasing the risk 22-fold among men and ninefold among women [10]. Data relating to the same group also showed that there was an apparent temporal relationship between tobacco consumption and changes in the incidence of primary sponta-

**Fig. 44.3** Suspended spring showing effects of increased tension in the upper coils.

neous pneumothorax in the community, a decrease in consumption being followed by a decrease in incidence within 1–2 years [34]. It is conjectured that the repeated stress imposed upon the walls of a pulmonary bleb by a smoker's cough might make it more likely to rupture. A causal relationship between the presence of a sharp inner border to the first or second ribs and primary spontaneous pneumothorax has been proposed [35]. This finding was present at thoracotomy in 49% of a series of 57 cases compared with only 8% of control subjects coming to thoracotomy for other reasons. It has been claimed that patients presenting with primary spontaneous pneumothorax are more likely to have minor bronchial anomalies at endoscopy than controls [36] and these patients are also more likely to show localized emphysema-like changes on CT, particularly in the upper zones and towards the lung periphery [37].

#### **Secondary spontaneous pneumothorax** (Table 44.1)

Spontaneous pneumothorax that occurs as a result of disease is categorized as secondary. Although it is less common than the primary form in developed countries, accounting for about one-third of cases [38], this may not be the case in those parts of the world where the prevalence of pulmonary tuberculosis remains high. With this possible exception, chronic bronchitis and emphysema are the most frequently associated conditions, accounting for

30–50% of cases in this group [4,33]. As these patients tend to be middle-aged or elderly, emphysema is the most common cause of pneumothorax in patient over 40 years of age [39]. Spontaneous pneumothorax has been recorded in 0.8% of a series of 1714 patients admitted to hospital with acute exacerbations of chronic bronchitis and emphysema [40]. Emphysematous bullae on the plain chest radiograph are frequently evident but this is by no means always the case [41]. In emphysema the leakage of trapped air through the weakened walls of dilated airspaces is probably assisted by the high intrabronchial pressures produced as a consequence of repeated coughing. It is also evident that pneumothorax may occur in association with large congenital bullae or cysts and in the absence of airflow limitation.

In one series, pneumothorax was reported to complicate 1.4% of cases of active tuberculosis [42]. Over 90% of these were cavitating and the pneumothoraces were thought to have resulted from the breakdown of tuberculous lesions situated close to the visceral pleura. It was observed that this might have been a more frequent complication had the overlying pleura not been thickened by fibrosis: when the pneumothorax did arise, the fibrosis caused it to be localized and limited in size. Before the advent of effective antituberculous chemotherapy, pneumothorax was frequently accompanied by a persistent bronchopleural fistula and tuberculous empyema with a mortality rate of 30–50% [43]. Pneumothorax has also been described in association with miliary tuberculosis but this is a rare complication [44].

Pneumothorax occasionally complicates asthma, having been found in 0.8% of 2000 adult asthmatics and 2.6% of 269 children admitted to hospital with severe asthma [45,46]. A more recent review of the chest radiographic findings of 1016 adult patients with asthma that was severe enough to require hospital admission in a large city in the UK found only one case (0.1%) of complicating pneumothorax [47].

Suppurative disease of the lungs and pleurae, particularly staphylococcal and *Klebsiella* pneumonia, is associated with pneumothorax. In the former, multiple lung abscesses may lead to the formation of cystic spaces or pneumatoceles that sometimes rupture into the pleural cavity, although such pneumatoceles are rare in adult compared with paediatric practice [48,49]. Prior to the availability of modern antibiotics, pneumothorax complicated approximately 5% of cases of staphylococcal pneumonia in adults and over 30% of cases in children [50,51]. Staphylococcal pneumonia continues to be the leading cause of pneumothorax in children and infants beyond the neonatal age group.

With the increasing prevalence of human immunodeficiency virus (HIV) infection, pneumothorax has become recognized as an important complication that occurs in approximately 2–4% of patients with AIDS, over 90%

of pneumothoraces in this condition being associated with active or previous episodes of *Pneumocystis carinii* pneumonia [52,53]. The chances of a patient with AIDS-associated *Pneumocystis* pneumonia developing a pneumothorax have been found to be about 6–9% [54]. One North American series of 120 patients with spontaneous pneumothorax referred to a surgical unit found that 27% of them had AIDS [55]. Patients with AIDS may be subject to bullous changes that have been termed ‘premature emphysema’ and *Pneumocystis* pneumonia itself has been shown to produce cystic changes on CT that persist despite clinical recovery [56]. Spontaneous pneumothoraces in AIDS are more commonly bilateral than is the case with other predisposing conditions, occurring in both lungs simultaneously in 34% according to one reported series [55]. It has been suspected that aerosolized pentamidine might predispose to spontaneous pneumothorax, although doubt remains on this score [53,57].

Patients with cystic fibrosis have a high incidence of spontaneous pneumothorax, which increases with age and which is an important cause of morbidity and mortality in this group (see Chapter 30) [58,59].

All other causes of secondary spontaneous pneumothorax may be regarded as unusual or rare. The diseases responsible include diffuse pulmonary inflammation of varying severity, which may be associated with fibrosis and cyst formation (honeycomb lung), and more localized disease processes abutting the pleural surface. Individual case reports abound and the following list is not exhaustive: cryptogenic fibrosing alveolitis [60]; occupational lung disease, particularly acute silicosis and Shaver’s disease [61,62]; granulomatous disease such as sarcoidosis, usually at a late and fibrotic stage [63] but occasionally at an early stage of active inflammation [64]; Langerhans-cell histiocytosis (histiocytosis-X) [65] and Wegener’s granulomatosis [66]; rheumatoid disease [67]; systemic sclerosis [68]; haemosiderosis [69]; lymphangioliomyomatosis [70,71]; pulmonary alveolar proteinosis [72]; inherited disorders of connective tissue such as Marfan’s syndrome [73], Ehlers–Danlos syndrome [74] and the marfanoid hypermobility syndrome [75]; other hereditary conditions, including neurofibromatosis [76] and tuberous sclerosis (which has been linked with lymphangioliomyomatosis) [77,78]; coccidioidomycosis [60,79]; parasitic infections of the lung including hydatid disease [80]; intrathoracic tumours, particularly metastatic sarcomas and germ cell tumours [81,82]; primary bronchial carcinoma [83]; malignant mesothelioma of the pleura [84]; and cavitating pulmonary infarction [85]. Pneumothorax has been seen with septic pulmonary emboli occurring as a complication of staphylococcal tricuspid endocarditis in drug addicts using intravenous heroin [86]. Infection or inflammation in the gastrointestinal tract may unusually result in pneumothorax that may complicate retropharyngeal abscess formation [87]. Fistulous communications

have also been described between benign gastric ulcers and the pleural cavity across an anatomically intact diaphragm [88] and between stomach, colon and the pleural cavity in the presence of congenital diaphragmatic herniae [89,90]. Pneumothorax has also been recorded in association with hyperinflation and cystic changes occurring distal to congenital bronchial atresia [91]. Radiotherapy used to treat Hodgkin’s disease above the diaphragm using a ‘mantle’ field may be complicated by pneumothorax [92,93].

Recurrent pneumothorax associated with menstruation was first reported by Maurer and is known as catamenial pneumothorax [94,95]. This rare condition, which is the usual way in which the thoracic endometriosis syndrome declares itself, is right-sided in about 90% of cases and is associated with multiparity, the pneumothorax occurring within 24–72 h of the onset of menstruation. Symptomatic pelvic endometriosis may be present in one-third to half of patients [96,97]. Examination of the diaphragm has occasionally revealed bluish cystic implants of endometrial tissue and there may be tiny diaphragmatic fenestrations through which it is supposed that endometrial tissue may find its way from the pelvis to the pleural cavity [98,99]. Less frequently the thoracic endometriosis syndrome presents as haemoptysis, sometimes in the presence of lung nodules consisting of islands of intrapulmonary endometrial tissue that may reach the lung by microembolization through the pelvic veins [100].

### Traumatic pneumothorax

Traumatic pneumothoraces may arise from the penetration of the pleural cavity as a result of stab or gunshot wounds or from its accidental puncture by needles or cannulae. It may also occur in closed or blunt chest injury such as may result from road traffic accidents or explosions [101,102]. In this situation, rib fractures and bronchial rupture are frequent findings, as is blood loss into the pleural cavity resulting in haemopneumothorax [103,104].

### Iatrogenic pneumothoraces

Iatrogenic pneumothoraces are common [105]. A 5-year study from a Veterans Administration medical centre in California found iatrogenic pneumothoraces to be slightly more common than the spontaneous variety; one-third were caused by transthoracic needle aspiration biopsy of suspected lung disease, 28% by thoracentesis and 22% by attempts to cannulate the subclavian vein [106].

About 12% of thoracenteses carried out on medical services result in pleural air leaks and pneumothoraces, although these are often shallow [107,108]. The frequency with which pneumothorax occurs may be increased further by closed needle biopsy of the pleura, although

rates of 8% or less are achieved as the experience of the operator increases [108]. Pneumothorax is also a common complication of the placement of intercostal tubes intended for the drainage of malignant pleural effusions. The pneumothorax rate was found to be 31% in 88 such patients when drainage of pleural fluid was being effected by a small-bore tube [109]. None of these pneumothoraces were associated with tension or respiratory distress, the tendency being for them to either resolve spontaneously or remain stable [109].

Pneumothorax is an accepted but unwelcome complication of percutaneous lung biopsy by any form of needle or trephine (see Chapter 8), occurring in 20–45% of patients. In some but not all studies, the rate of pneumothorax has been found to be greater with increasing distance of the target lesion from the chest wall and also with smaller lesions, which may require more needle passes to locate them [110–113]. Lower complication rates have been obtained when a fine-gauge needle is employed [110,114], and lower rates may also be obtained when a modern gun-actuated cutting needle is used [115,116]. These accidental pneumothoraces are generally shallow but when they do occur chest tube placement has been recorded as necessary in 10–30% of cases [111,116]. Some investigators have found that the probability of pneumothorax is increased not only by greater depth of penetration of the needle but also by the presence of an obstructive impairment of ventilatory capacity [110,117]. Others have found that an obstructive impairment of lung function does not reliably predict complicating pneumothorax, although when pneumothorax does occur the need for tube placement clearly depends on the severity of any pre-existing pulmonary impairment [110–113]. It has been claimed that if the patient breathes pure oxygen before lung biopsy, the frequency of complicating pneumothoraces is reduced [118]. However, Poe and colleagues [117] observed an unaltered risk after breathing oxygen, although the size of the pneumothorax was reduced and the rate of its absorption increased.

Subclavian vein cannulation, with location of the vein by surface landmarks, is commonly used for measurement of central venous pressure, the administration of high-dose chemotherapy and long-term antibiotics, and total parenteral nutrition. A prospective study of 821 subclavian vein catheterizations found the overall pneumothorax rate to be 1.5% [119]. The complication rate increased with the number of passes, if body mass index was greater than 30 or less than 20 and if the patient had undergone prior surgery or radiotherapy to the ipsilateral hemithorax. The complication rate was not reduced by the use of ultrasound to help localize the vein [119]. Sometimes such pneumothoraces are 'delayed' and are not evident on the radiograph taken immediately after catheterization [120].

Pneumothorax is the most common complication of transbronchial lung biopsy, occurring in about 2–5% of

cases or in a higher proportion if fluoroscopy is not used (see Chapter 8). Although pneumothorax in this situation is usually an immediate complication, it may occasionally be delayed by hours or even days [121]. The diagnostic yield of routine chest radiographs is very low in patients who have just undergone fluoroscopically guided transbronchial lung biopsy but who have no symptoms or fluoroscopic findings suggestive of pneumothorax, no unsuspected pneumothorax being found in 305 consecutive procedures in a study from the University of Virginia [122].

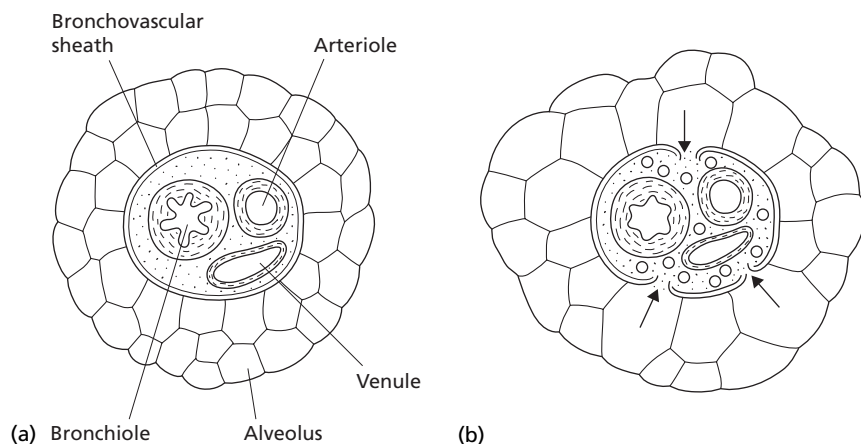

Pneumothorax may also complicate needle biopsy of the mediastinum, breast and liver [123–125], and may occur following tracheostomy [126].

Traumatic pneumothorax has also been described following a further miscellany of procedures, including acupuncture of the thoracic wall [127], the surgical use of a laser beam in the upper respiratory tract [128,129] and the misplacement of a small-bore nasogastric feeding tube in the respiratory tract [130]. Oesophageal rupture resulting from instrumental or other trauma may lead to pneumothorax in association with mediastinitis [131]. Pneumothorax may be self-inflicted by drug addicts who, having used all accessible veins in the arms, may resort to the practice of internal jugular or subclavian vein injection ('pocket shooting') [132,133]. The author has also seen traumatic pneumothorax occurring as a form of deliberate self-injury in a patient with psychological problems and access to hypodermic needles.

### Pulmonary barotrauma

Since the volume of a given mass of gas at a constant temperature is inversely proportional to its pressure (Boyle's law), so a given volume of air, saturated at 37°C, expands to approximately 1.5 times the volume it would have occupied at sea level if it is placed at an altitude of 3050 m. Should the air in question be trapped in a pleural bleb, the expansive force may cause that bleb to rupture into the pleural cavity resulting in a pneumothorax. Individuals who may be subject to such decompression occurring suddenly and by accident include aircrew, in whom radiographic screening procedures have been employed to exclude blebs prior to acceptance for flight training [134].

Considerable pressure changes may also occur underwater (see Chapter 57). The atmospheric pressure on the surface of the sea is 101 kPa (760 mmHg) but this increases linearly and doubles with every 10 m of descent. During scuba (self-contained underwater breathing apparatus) diving, in which compressed air is delivered to the lungs from a cylinder via a demand regulator, it is during ascent that barotrauma may occur: as ambient pressure falls rapidly, so gas contained in the lungs expands and serious damage may occur [135]. Such injury can be avoided if the diver is taught never to breath-hold and to ascend slowly,

**Fig. 44.4** Barotrauma resulting in pneumomediastinum: (a) normal situation; (b) distended gas-containing spaces with air tracking from ruptured alveoli into the connective tissue plane of the bronchovascular bundle from which it may travel to the mediastinum and beyond. (After Maunder *et al.* [138].)

giving time for the expanding gas to escape by exhalation. Similarly, submariners who have to surface rapidly in submarine escape tank training must never do so with the glottis closed but must be taught to exhale continuously during ascent in order to allow the expanding intrathoracic gas to vent [136,137]. Caisson workers are at similar risk from rapid decompression.

Under all these circumstances expanding gas may break through both alveoli and subsequent anatomical barriers: 1 the visceral pleura to produce pneumothorax (which may be bilateral);

2 the bronchovascular bundle (Fig. 44.4) to produce mediastinum;

3 the connective tissue continuum leading from the mediastinum to the neck and beyond, producing subcutaneous emphysema; and

4 the diaphragmatic hiatus, entering the peritoneal cavity and more rarely tracking between the diaphragm and the parietal pleura to produce encysted pockets of gas at the lung bases.

Much more seriously, rapidly expanding gas that has escaped from ruptured alveoli may track back into torn pulmonary veins, resulting in systemic arterial air embolism [139].

Pneumothorax due to barotrauma may also occur in patients who require positive-pressure mechanical ventilation, although this correlates most closely with the nature of the underlying disease. This is a particular problem in patients with adult respiratory distress syndrome (ARDS) [140,141]; 17% of 41 patients with ARDS receiving high-level ( $>15\text{ cmH}_2\text{O}$ ) positive end-expiratory pressure ventilation developed radiographic signs of barotrauma including pneumothorax in one recent series [142]. Barotrauma may also occur as a result of attempted cardiopulmonary resuscitation [143]. Endotracheal tube misplacement, which is common, may also increase the chance of barotrauma by directing an excessive blast of air to one lung [144]. Systemic arterial air embolism has also occurred as a result of ventilator-associated barotrauma in

association with ARDS and necrotizing pneumonia, but is rare [145].

There have been a number of reports of spontaneous pneumothorax occurring during the inhalation of recreational drugs, such as crystalline free base cocaine ('crack') and cannabis (marijuana, hashish, 'dope', 'pot', 'grass', 'ganja', 'hash'). The former, which looks like small crystals ('rocks'), may be smoked in a pipe or the vapour may be inhaled from a piece of heated tin foil, in contrast to cocaine powder which is taken like snuff. Cannabis is usually smoked mixed with tobacco in a rolled cigarette. Those pneumothoraces that have been described may result from a form of barotrauma, in both cases possibly being related to coughing or straining while the user is breath-holding after a deep inhalation near total lung capacity [146,147]. Pneumothorax due to presumed barotrauma has also been reported with the use of tracheo-oesophageal voice prostheses by patients who have had a total laryngectomy for carcinoma of the larynx [148].

### Artificial pneumothorax

This term refers to the deliberate introduction of a measured volume of air into the pleural cavity by needle, using a device such as that illustrated in Fig. 44.5. Devised by Forlanini in the nineteenth century, this procedure became a popular method of treatment for pulmonary tuberculosis in the era before antibiotics but is now obsolete, although the technique is still employed diagnostically in order to enable the thoracoscopist to visualize the surface of the lung and postoperatively in order to test whether a chemical or surgical pleurodesis has been effective [149].

### Physiological disturbance

When pneumothorax occurs in a previously healthy subject, a restrictive impairment of ventilatory capacity is produced with a reduction in vital capacity, functional

**Fig. 44.5** Maxwell box used to induce artificial pneumothorax for the treatment of tuberculosis before the introduction of chemotherapy.

residual capacity and total lung capacity commensurate with the size of the pneumothorax [150]. There may also be a small reduction in diffusing capacity for carbon monoxide ( $DL_{CO}$ ) and increase in the transfer coefficient ( $K_{CO}$ ) [151]. If the pneumothorax is large, with greater than 20% collapse, then  $PaO_2$  falls immediately before returning to normal over the space of a few hours, despite the fact that the size of the pneumothorax may remain the same [152,153]. The initial hypoxaemia results from the shunting of blood through deaerated lung. The subsequent return to normoxaemia despite persisting lung collapse results from compensatory vasoconstriction that abolishes gross ventilation-perfusion mismatching in the affected lung [154]. Pulmonary function almost always returns to normal following re-expansion of the collapsed lung and although minor defects of gas distribution and reduced pulmonary compliance have been recorded, they appear to be of no clinical significance [155].

In tension pneumothorax the physiological disturbance may be severe and life-threatening. A valve-like tear in the visceral pleura permits air to progressively fill the pleural cavity during each inspiratory effort. As the intrapleural pressure builds up, hypoxaemia results from compression of both the ipsilateral and contralateral lung and the mediastinal structures are displaced across the midline. This mediastinal displacement and compression may cause a fall in cardiac output leading to hypotension and syncope.

Experiments with dogs have shown that the induction of pneumothorax in the conscious animal results in hyperventilation with arterial normoxaemia and hypocapnia. The belief that this behaviour is in part neuronally mediated is supported by the observation that when the same procedure is carried out in the vagotomized dog, hyperventilation does not occur and hypoxaemia ensues. General anaesthesia also impairs this adaptive response [156]. The relevance of these findings to the physiological consequences of pneumothorax in humans is unclear.

A study of regional lung function in spontaneous pneumothorax showed uniform airway closure on the affected side at low lung volumes, leading to the suggestion that

this was the chief cause of ventilation-perfusion mismatch [157].

## Clinical features

### Symptoms

The most common mode of presentation is for a previously fit young man to develop sharp unilateral chest pain. This is frequently accompanied by shortness of breath, although pain may be the sole presenting symptom in two-thirds of patients [158]. The pain may be continuous but tends to be exacerbated by deep inspiration and postural change. It is often of moderately severe intensity but is sometimes insufficiently troublesome to cause the patient to seek medical advice for several days [159]. It is common for the pain to settle within a day or so, despite the persistence of the pneumothorax on the chest radiograph. Very occasionally a pneumothorax may be found unexpectedly on a chest film taken for routine reasons in a symptom-free individual. This suggests that spontaneous pneumothorax may occur more frequently in the population than is realized and that it may resolve unnoticed. The majority of cases of spontaneous pneumothorax are unassociated with physical exertion [33,160,161].

Extreme dyspnoea in a previously healthy subject is unusual and implies that the pneumothorax is under tension. In this situation the patient is anxious, restless and tachypnoeic, struggling for breath. Unless tension is relieved the patient may worsen, developing a rapid low-volume pulse and hypotension. Dyspnoea may be equally extreme with only a small pneumothorax; when this occurs in patients whose lung function is already impaired by underlying disease and in order that serious and unnecessary mishaps may be avoided, it is essential for clinicians to be alert to the possibility of pneumothorax when assessing a deteriorating patient with known asthma or chronic obstructive airways disease.

In the majority of patients the pneumothorax is small;

when this is the case, the presenting symptoms subside within a few hours even though there has been little or no radiographic improvement. Cough is not a prominent feature unless related to coincidental disease and when present is usually dry [17].

Spontaneous bilateral pneumothorax is rare [38,162,163], occurring in subjects who rupture bilateral apical blebs simultaneously or in patients with extensive bilateral emphysema or other cystic lung disease. It may be rapidly fatal [164].

### Physical signs

A small pneumothorax may be impossible to detect on physical examination. If a sufficient volume of air enters the pleural cavity it insulates the lung from the stethoscope, producing the classical diagnostic signs described by Laënnec, comprising unilateral absent or diminished breath and voice sounds in the presence of a normal or hyperresonant percussion note [165]. Other signs are less important but complementary. Chest movement may be diminished on the affected side. When tension is present the chest may appear larger ipsilaterally and the mediastinum may be pushed to the opposite side, resulting in displacement of the trachea and apex beat. Similarly if the pneumothorax is right-sided, the liver may be displaced downwards so that the upper level of hepatic dullness moves caudally. There may be jugular venous engorgement.

A crepitous sound may be heard over the precordium and is sometimes even noticed by the patient. This noise is referred to as a 'mediastinal crunch' and may occur throughout the cardiac cycle, being influenced in its intensity by posture and the phase of respiration. It was described by Lister [166] in association with left-sided pneumothorax and later by Hamman [167], who considered it to result from free air in the mediastinum (Hamman's sign). In fact it may occur in both conditions, resulting from the close proximity of trapped air to moving heart muscle, and is not pathognomonic of pneumomediastinum. It has also given rise to the terms 'noisy' or 'clicking' pneumothorax [168,169]. Leakage of air into the mediastinum may spread to the subcutaneous tissues of the neck and beyond producing the characteristic palpable crepitus of 'surgical' emphysema, which may spread further to involve the face, anterior chest wall and beyond, sometimes alarming both onlookers and the patient who may quite suddenly come to resemble the 'Michelin man' of advertisement fame. Both may be reassured since this impressive sign is of no particular prognostic significance.

The signs of an associated pleural effusion or haemothorax are likely to be overlooked unless it is of moderate size, in which case in addition to the more usual physical signs devotees of medical history may perform Hippocratic

succussion, in which a splashing sound is produced by rocking the patient to and fro [170]. The coin test is another obsolete manoeuvre, although the 'scratch sign' is sometimes usefully employed. In this test the stethoscope is placed in the mid-point of the sternum and the surface of the chest wall scratched with the finger at points equidistant to the left and right of the instrument. The sound heard is louder when the side of the pneumothorax is scratched [171].

The occurrence of pneumothorax in a mechanically ventilated patient may be suggested by (i) the sudden onset of tachycardia and hypotension, caused by a tension pneumothorax impeding venous return; (ii) an increase in peak airway pressure, resulting from external lung compression; (iii) a sudden decline in oxygen saturation; or (iv) the distressed patient appearing to 'fight the ventilator'.

### Radiographic appearances

The characteristic finding is a sharply defined lung edge that is convex outwards and separated from the chest wall by a lucent zone entirely devoid of lung markings (Fig. 44.6). The thin white line representing the lung margin may be overlooked if the pneumothorax is shallow, in which case it may be hidden by bony shadows particularly if it is apical, as it may well be on an erect posteroanterior chest radiograph. If a pneumothorax is suspected clinically but cannot be detected on a standard inspiratory film, then two procedures may be used to confirm or refute the diagnosis. In the first the chest radiograph is taken in full expiration. This has the effect of reducing the volume of both the thorax and the partially deaerated lung. As the volume of gas contained within the pleural cavity is incompressible at physiological pressures, it remains the same on expiration and the pneumothorax therefore appears to enlarge in relation to the smaller thoracic volume (Fig. 44.6). In the second method the chest radiograph is taken in the lateral decubitus position with the side on which the pneumothorax is suspected uppermost [172]. Even a small pneumothorax is revealed by this technique as the air-lung interface becomes clearly visible beneath the lateral chest wall. This is also the preferred view for demonstrating pneumothorax in infants. In complete pneumothorax the lung appears as a dense globular shadow at the hilum (Figs 44.2 & 44.7). However, with lesser degrees of collapse the density of the lung may vary little from that of the fully expanded viscus. This finding is probably the result of a commensurate reduction in pulmonary blood flow [173]. Sometimes increased blood flow to the opposite lung may produce exaggerated vascular markings that may be mistaken for pneumonic shadowing.

In a tension pneumothorax the lung may be compressed into a shapeless shadow or even displaced across the

(a)

(b)

**Fig. 44.6** (a) Respiratory and (b) expiratory films showing apparent enlargement of left pneumothorax on expiration.

**Fig. 44.7** Tension pneumothorax showing small dense shadow of collapsed left lung and deviation of mediastinum to the right. There is gross overdistension of the left thoracic cavity.

midline along with the mediastinal structures (Fig. 44.7). In addition, the diaphragm may be depressed so that its costal attachments become clearly visible. It should be noted that some degree of mediastinal displacement is to be expected on an expiratory film and that this does not indicate tension. Some mediastinal displacement is also commonly seen in large pneumothoraces in the absence of *clinical* signs of tension such as tachypnoea and hypotension. When there is also fluid as well as air in the pleural cavity it appears as a completely horizontal line with no meniscus where it abuts the lateral chest wall (Fig. 44.8) and this finding may draw the observer's attention to the presence of a small pneumothorax that might otherwise have been missed.

It has been suggested that CT may be useful in the unusual case where the distinction between a bulla and a pneumothorax cannot be easily made but in practice this is seldom necessary [102].

In patients under intensive care only supine films may be available for interpretation. In this situation a pneumothorax may be indicated by increased lucency on the ipsilateral side due to an anterior collection of gas, and by a deep lateral costophrenic angle also on the involved side. This last feature has been called the 'deep sulcus sign' and

when present should lead to a request for a lateral decubitus or 'cross table lateral' view to confirm [174].

### Differential diagnosis

Although the differential diagnosis includes many conditions associated with chest pain and dyspnoea, in practice few difficulties are encountered. Pain due to myocardial infarction, pleuritis associated with pulmonary infarction or pleural infection, and the pain of intra-abdominal inflammatory disease, such as a perforated peptic ulcer, may occasionally suggest pneumothorax to the clinician but any doubts should be resolved by physical examination and the chest radiograph. It should be noted that changes in the ECG typical of a transmural myocardial infarction may be produced by a left-sided pneumothorax, although these changes resolve once re-expansion has occurred [175]. A breathless patient with generalized emphysema may have physical signs that give rise to confusion with pneumothorax but again the chest film is generally diagnostic. Where a massive emphysematous bulla or congenital lung cyst occupies a large part of one hemithorax, the physical signs may be indistinguishable from pneumothorax and even the chest radiographic

**Fig. 44.8** Right hydropneumothorax showing basal fluid level.

appearances may not be dissimilar (Fig. 44.9). It is on such occasions that time taken to enquire about or to obtain previous chest radiographs is time well spent (Fig. 44.10). A lateral decubitus view is often helpful in differentiating an upper lobe bulla or cyst from a typical pneumothorax; in the first case, the gas is constrained by the anatomical boundaries of the upper lobe, whereas in pneumothorax it usually moves to lie along the lateral chest wall. The herniation of a large volume of gut through a diaphragmatic defect may also mimic the physical signs of a basal pneumothorax. Such defects may be congenital or acquired, in which case a history of recent or remote trauma to the lower chest or abdomen (e.g. road traffic accident) might be obtained. When radiographic uncertainty exists, barium contrast studies of the upper or lower bowel are diagnostic.

It is emphasized that pneumothorax should always be considered when patients with previously diagnosed lung disease, such as asthma or chronic obstructive pulmonary disease, present with an apparent deterioration.

### **Management of spontaneous pneumothorax**

There is evidence of considerable variation in individual management of spontaneous pneumothorax, thoracic sur-

geons on the whole tending to resort to more active measures than physicians [176].

### **Conservative management**

Conservative management relies upon the natural tendency of the gases in a pneumothorax space to be reabsorbed and has the attraction of avoiding any form of invasive procedure [177,178]. This approach is indicated in an otherwise healthy adult who is not breathless and in whom the volume of the pneumothorax is judged to be small. 'Small' is widely taken to mean that the pneumothorax occupies less than 20% of the hemithoracic volume. Various methods for calculating the volume of a pneumothorax have been published [179,180] but these are rarely used in practice. Thus most clinicians leave a primary spontaneous pneumothorax that they gauge as shallow, treating those that are moderate or large [181]. As a rule of thumb, if the lateral edge of the lung is separated from the ipsilateral chest wall in the horizontal plane and at the widest point of the pneumothorax by more than one-third of the transverse diameter of the hemithorax, then the pneumothorax can be regarded as moderate to large and active treatment is reasonable. Previously healthy patients with small spontaneous pneumothoraces need not be admitted to hospital and rest in bed is not manda-

**Fig. 44.9** (a) Large, presumably congenital, bulla in asymptomatic young woman mimicking pneumothorax. (b) Same patient after excision of bulla showing expansion of normal lung.

tory. Non-manual work may be continued but heavy physical exertion should be disallowed. The chest radiograph should be repeated at weekly intervals until full expansion has occurred; meanwhile the way should have been prepared for prompt admission should dyspnoea develop. If any doubt exists the safest course is to admit

and observe for 24 h in order to ensure that the pneumothorax is not enlarging. Patients with significant underlying lung disease such as emphysema should be admitted for observation even if the pneumothorax is shallow, since these patients are at risk of developing severe respiratory failure if the pneumothorax enlarges.

**Fig. 44.10** Somewhat similar appearance to that in Fig. 44.9a but due to a tethered pneumothorax. A previous film showed no abnormality.

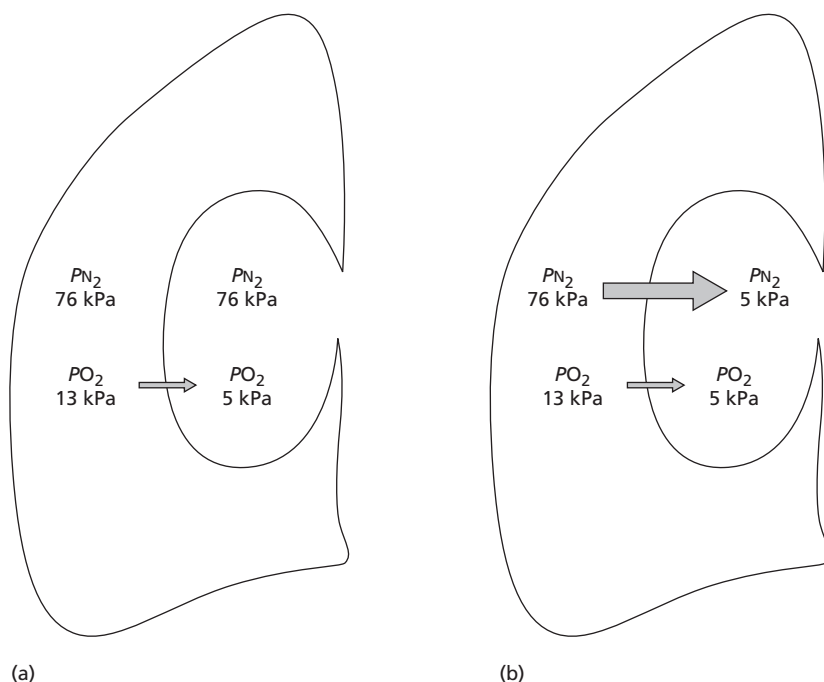

Provided the pneumothorax remains 'closed', the lung will re-expand slowly. This is because the rate of transfer of gases across a semi-permeable membrane is directly proportional to the difference in partial pressure of the gases on either side of the membrane. The total gas pressure of alveolar air is approximately 101 kPa (760 mmHg) at sea level, this being the same as the arterial total gas pressure; however, the venous total gas pressure is about 93.8 kPa (705 mmHg) due to the fall in  $P_{O_2}$  from approximately 13.3 kPa (100 mmHg) in the arterial system to 5.3 kPa (40 mmHg) in the venous system, the balance being due to the smaller rise in  $P_{CO_2}$  between the arterial and venous phases. Kircher and Swartzel [179] described a radiographic method to express the volume of pneumothorax as a percentage of hemithoracic volume and found an average rate of re-expansion of 1.25% hemithoracic volume per day. Thus, provided that there is no further air leak, a '10% pneumothorax' re-expands in approximately 8 days, a '20% pneumothorax' in 16 days, and so on.

Absorption of gas from a pneumothorax space may be hastened by breathing a high concentration of oxygen [180]. By breathing 100% oxygen instead of ambient air, which contains about 79% nitrogen, alveolar  $P_{N_2}$  falls and nitrogen is gradually washed out of the tissues and vascular system as oxygen is taken up, so that the end-capillary total gas tension eventually falls from approximately 93.8 kPa (705 mmHg) to around 22.6 kPa (170 mmHg). This produces a substantial gradient between the tissue capillary (low  $P_{N_2}$ ) and the pneumothorax space, which is nearer atmospheric pressure (about 101 kPa, relatively high  $P_{N_2}$ ), with the result that the rate of absorption of gas

from the pleural space increases several fold (Fig. 44.11). Clearly, high concentrations of oxygen are contraindicated in those patients with chronic obstructive pulmonary disease whose respiratory centres may be dependent upon 'hypoxic drive'; furthermore, the potential toxicity of high concentrations of oxygen for prolonged periods in otherwise healthy individuals has to be considered [182]. However, oxygen therapy may be a useful adjunct to the conservative treatment of pneumothorax in patients who also have a bleeding diathesis in order to avoid an invasive procedure such as tube drainage with its attendant risk of haemorrhage.

### Active management

Most reported hospital series show that in the majority of patients the volume of the pneumothorax exceeds 20%, fitting into the moderate or large categories mentioned above. Brooks [163], while acknowledging the difficulties in estimating size, reported 23% of patients presenting with 25% collapse, 31% with 25–50% collapse, 13% with 50–75% collapse and 33% with over 75% collapse in his series of 376 spontaneous pneumothoraces. In view of this, active treatment in hospital is employed in the vast majority of cases in order to achieve full expansion within a reasonable length of time. Hospital treatment is indicated not only for moderate or large primary spontaneous pneumothoraces but also for secondary spontaneous pneumothoraces, in which underlying lung disease is associated with a pre-existing impairment of lung function so that even a shallow pneumothorax may be serious.

**Fig. 44.11** Potential partial pressure differences for oxygen and nitrogen between a closed pneumothorax space and venous end capillaries that contribute to reabsorption of gas when the patient breaths (a) ambient air and (b) a high concentration of oxygen so that nitrogen is 'washed out'. The differences in  $P_{CO_2}$  are relatively small and are not illustrated. (a) No difference in  $P_{N_2}$ , small differences in  $P_{O_2}$ . (b) Large difference in  $P_{N_2}$ , small differences in  $P_{O_2}$ .

### Aspiration

The insertion and removal of a standard intercostal drain is unpleasant for the patient and while the drain remains *in situ* regular analgesia is required. In view of this, simple manual aspiration has been re-evaluated [183,184]. The technique originally employed a needle and attracted condemnation because of the risk of lacerating the lung as it expanded [162,185]; however, this complication may be avoided if a modern plastic intravenous cannula is used and various clinicians have claimed success for their techniques [186–189]. The author prefers a small (8 cm long, 10 French gauge) neonatal pneumothorax cannula with trocar and side-holes as well as an end-hole. The second intercostal space in the mid-clavicular line is conventional, although an axillary approach in the fourth, fifth or sixth space between the mid and anterior axillary lines may be used as an alternative. The cannula is inserted aseptically with local anaesthetic and air withdrawn and expelled using a large Luer-Lok syringe with a three-way tap. Placement of the exit tube underwater reduces the chance of an embarrassing mistake. Provided that the patient's condition remains stable, the procedure may be continued until no more air can be withdrawn or until 3 L has been removed, which implies that a leak is still present. Aspiration is abandoned and an intercostal drain inserted if the patient's condition deteriorates.

Simple aspiration is contraindicated if the patient is distressed as a result of a tension pneumothorax or when there is more than a little pleural fluid present. It is unnecessary if the pneumothorax is shallow. For the remainder, while aspiration may avoid the need for an intercostal

drain in a significant number of patients [188], those in whom the technique fails due to reaccumulation of air require treatment by conventional means and their hospital stay is likely to be longer than would otherwise have been the case. A marker gas technique may be used in order to determine whether the pleural leak has sealed off at the time of aspiration, chest radiographs taken immediately after aspiration being unreliable in this respect. The hydrocarbon propellant gas found in metered-dose inhalers has been used in this way, being detected by a portable flame ionizer [190], the patients' breathing from a Douglas bag containing air or oxygen labelled with the tracer gas (Fig. 44.12). Those pneumothoraces that were negative for tracer gas were successfully treated by aspiration, whereas those that were positive for tracer gas frequently recollapsed over the following 12 h despite initial radiographic improvement, requiring tube placement in 60–80% of cases [191,192]. Patients negative for tracer gas may be discharged early if their general condition allows, provided that arrangements for prompt readmission have been put in place should the need arise [192].

There is evidence to suggest that patients who are treated by aspiration not only experience less pain but are also likely to spend a shorter time in hospital than those treated by intercostal tube drainage [192,193]. Manual aspiration is less likely to be successful in pneumothoraces in which the lung is completely collapsed at presentation [194]. When taking the requirement for a chest drain as the end-point, the marker gas technique has subsequently been found to have a negative predictive value of 95% and a positive predictive value of 67% when applied to 136 events.

Failed manual aspiration

### Intercostal tube drainage

When simple manual aspiration is contraindicated, the preferred method of treatment is intercostal tube drainage or 'tube thoracostomy', in which an intercostal drain is inserted into the pleural space and connected to an underwater seal bottle (Table 44.2).

It has been suggested that premedication with atropine 0.6 mg i.m. might reduce the chances of a vasovagal reaction. A common site for insertion is in the second intercostal space in the mid-clavicular line, thereby avoiding the internal mammary arteries (which run vertically 3–4 cm to the left and right of the sternum, posterior to the costal cartilages). The first intercostal space is immediately below the clavicle and is avoided because of the risk of major neurovascular damage; the second intercostal space is identified below the second rib, which articulates with the sternal angle of Louis.

An alternative site now commonly used and which may be preferred in women for cosmetic reasons is the fourth or fifth intercostal space between the anterior and posterior axillary lines. This site is also suitable when the pleural cavity contains fluid, because drainage is facilitated, and is also preferred in traumatic pneumothorax.

The choice of site may also be influenced by the presence of adhesions as seen on the chest radiograph. In order to avoid the upper limit of the diaphragm, it is a good rule for the physician not to insert a tube below nipple level in the male or below the sixth space in the female.

Once the entry point has been selected and the site marked with a pen, 10–15 mL of 1% lidocaine (lignocaine) is infiltrated from the skin to the parietal pleura, taking in the periosteum of the upper border of the rib at the chosen interspace and localizing the pneumothorax space by withdrawing air. This is done *before* skin preparation in order to give time for the local anaesthetic to have its effect. The needle can be left in place to mark the site of anaesthetic infiltration while aseptic skin procedures are then followed. A small (1–1.5 cm) incision is made through skin to subcutaneous fat over the body of the rib that lies below the chosen intercostal space. Two interrupted sutures, or better still a single central mattress suture, are inserted across the incision so that they can be tied later when the tube is removed. Purse-string sutures should be avoided as they may result in skin necrosis. A further silk or propylene securing suture (at least 0 gauge) is placed alongside the incision so that the drain can be tied in once inserted (Fig. 44.13). The track for the tube is made by blunt dissection with a haemostat (artery forceps). This is done by advancing the haemostat a short distance with the jaws closed, opening the jaws, withdrawing the instrument, closing the jaws and advancing it further [195]. The track is aimed obliquely upwards towards the upper border of the same rib, the objective being for the tube to follow this direction so that its tip lies at the apex of the hemithorax. The lower border of the rib above, with the neurovascular bundle lying behind its lower margin, is avoided.

The pleural cavity used to be routinely entered with a relatively short guarded steel trocar and cannula

(Fig. 44.14). Following withdrawal of the trocar, a rubber self-retaining Malecot catheter stretched on a steel introducer was passed through the cannula and the introducer and cannula then withdrawn. Nowadays Malecot catheters are virtually museum pieces and a prepacked disposable plastic tube with a long central metal trocar is usually provided instead; 18–24 French gauge is suitable for air, whereas if blood as well as air needs draining a larger tube (e.g. 28–32 French gauge) may be more successful. The central trocar on such modern tubes may have a conical point that does not cut tissues but spreads them, so that in less experienced hands and if undue pressure is applied this assembly carries the risk of causing injury to the lung or other tissues by sudden deep penetration of the

chest. This may be particularly relevant in cases of traumatic pneumothorax dealt with by accident and emergency personnel; in these patients diaphragmatic rupture may have occurred, allowing abdominal viscera such as the liver, spleen or stomach to lie within the thoracic cavity, so that various advanced life support guidelines recommend that intercostal drains should be inserted without a trocar in trauma cases (see p. 1204). A protective guard has been devised to prevent such sudden deep entry [196] (Fig. 44.14) but in truth heavy pressure should never be applied. Once the forceps have entered the pleural cavity by blunt dissection, the track may be widened with the forefinger if necessary so that the tube can then be easily introduced while being gripped firmly about 5 cm from its tip to allow for any loss of resistance when the pleural cavity is reached and to avoid sudden overpenetration. The trocar may be withdrawn a few centimetres and used to help angle the tube, which is advanced about 8 cm towards the apex. As an alternative, curved blunt plastic-coated metal introducers are also available that can be placed through a side-hole of the plastic drain in place of a trocar to enable it to be directed towards the apex of the lung. The trocar or introducer is then removed completely in order to allow the intercostal drain to be attached with a suitable untaped connection to further tubing, which joins it with an underwater seal drainage bottle. The catheter connected to the bottle passes through a double-lumen stopper or similar arrangement to rest 2.5 cm below the surface of about 0.5 L sterile water, thereby acting as a one-way low-resistance valve. Correct placement of the tube is greeted by a satisfying stream of bubbles during expiration or coughing and a rise in the level of the fluid in the underwater seal tube during inspiration.

All connections and tubing require regular inspection to avoid either leakage or blockage by kinking. So-called

**Fig. 44.13** Sutures inserted to secure the drain and for closing the wound when the drain is removed. The drain is secured to the skin by tying knots on either side of it. (After Parmar [195].)

**Fig. 44.14** Disposable plastic cannula, metal trocar and plastic guard (above) and early rubber Malecot catheter with steel introducer, trocar and cannula (below)

'sleek' should be avoided, and simple adhesive tape is used to cover the gauze skin dressings and may also be used to fashion a supportive mesentery for the tubing but should not conceal any junctions in the drainage system. The tube itself should be attached to the skin by knotting the securing suture three or four times on each side of the drain (Fig. 44.13), which should also be looped and taped to the skin to further reduce the chance of it being accidentally pulled out.

Should the patient be in a state of cardiovascular collapse as a result of a tension pneumothorax, release of the positive pressure in the pleural cavity is a matter of urgent necessity. Provided that there is no doubt about the diagnosis, this may be quickly achieved with rapid clinical improvement by the insertion of a wide-bore hypodermic needle or preferably a plastic intravenous cannula into the pleural cavity. This allows the pressure in the pneumothorax to become atmospheric and if the diagnosis was correct results in immediate improvement in the patient's condition so that an intercostal tube can then be inserted in a more orderly manner [197].

The application of suction to the second opening of the underwater seal drain bottle has been recommended by some in order to assist expansion of the collapsed lung. This has been applied either at constant high flow using an appropriate pump (e.g. Thompson or Tubbs-Barrett rather than Roberts) or at constant pressure (e.g. 1.5–5.0 kPa, 15–50 cmH<sub>2</sub>O) using wall suction with a pressure reducing valve. However, if the pneumothorax is closed this should be unnecessary as expansion will occur within 2–3 days anyway. If the pneumothorax is open then the application of suction at practicable flow rates might in theory prevent it from sealing off by drawing air through the point of leakage. This is in agreement with observations that mechanical suction does not influence the rate of re-expansion [198].

The tube is left *in situ* until the lung is fully re-expanded on the chest radiograph and the tube has not been seen to bubble for 24 h. Once this has been achieved, the tube may be removed. It is safer to remove tubes with the help of an assistant. One throw of the knot in the mattress suture is made. The patient inspires fully and is then asked to perform a Valsalva manoeuvre, thereby reducing the risk of air entering the pleura again as the drain is withdrawn. The drain is removed with one smooth quick movement while the track is compressed and the knot in the mattress suture is then completed [195]. Some practitioners prefer to clamp the tube for about 12 h once the tube has apparently stopped blowing and when no bubbles are seen on coughing, after which the intercostal tube is removed if the lung remains fully expanded. However, if the pneumothorax has reaccumulated, the clamp is removed and the air once again fully drained before the cycle is repeated. The obvious drawback of clamping is that the patient may become distressed if a substantial leak does

occur and the clamp is not removed promptly because of lack of understanding by staff either at the bedside or while the patient is being transported between departments; the British Thoracic Society guidelines thus advise against this practice [181].

It is usually possible to re-expand the lung and remove the tube within 3–4 days. Intercostal tubes may occasionally kink or become blocked by blood or fibrous material before full re-expansion has taken place. The column of water in the underwater seal drainage bottle is seen to stop swinging in this situation and the intercostal tube needs to be unkinked or replaced through a second clean incision in order to achieve a satisfactory result. Sometimes several such tube changes are required and re-expansion is slow. This is particularly common in patients with diffuse emphysema, although almost always in such cases if drainage is continued the leak eventually seals. A retrospective study of 214 patients with spontaneous pneumothorax found that 51% still had a persistent leak after 2 days of tube drainage. Of those who continued to be treated medically, the median time to resolution was 7 days for those with primary spontaneous pneumothorax and 11 days for those with underlying lung disease [199]. It has been claimed that patients with uncomplicated pneumothoraces treated by intercostal catheter are usually fit to return to work within 1 week [162]. Other authors have reported an average hospital stay of 13 days for cases of pneumothorax treated with underwater seal drainage [200].

### Flutter valves

Commercially available (Heimlich-type) flutter valves may be connected to the chest tube in order to avoid the encumbrance of an underwater seal drain [201,202]. This method has been used satisfactorily in battle casualties [201] and also in the civilian outpatient management of pneumothorax, sometimes by using narrow 8–14 French gauge intercostal catheters [203–207]. These valves may be more prone to blockage than standard underwater seal drainage [208] and their use in general management has not gained full acceptance. Prepacked water-free ambulatory chest drainage kits incorporating a conventional intercostal drain that connects to a plastic bag with an integral flutter valve are also available for use in trauma cases.

### Chemical pleurodesis

The tendency for a pneumothorax to recur (see p. 1202) has led to the development of certain procedures intended to cause the visceral pleura to adhere to the inner surface of the chest wall. Various foreign substances may be introduced into the pleural cavity in order to produce a sterile pleurisy, with the subsequent formation of adhesions between the visceral and parietal pleural layers [209].

This method, known as chemical pleurodesis, was first described by Spengler over 80 years ago [210]. The wide variety of different substances that have been used to achieve pleural symphysis, ranging from irritants such as tetracycline, 50% glucose solution, autologous blood and iodized oil to more caustic chemicals such as silver nitrate solution to physical irritants such as iodized talc slurry or kaolin and more recently to fibrin glue sealant, implies that the search for an ideal agent continues. These substances may be injected or insufflated through an intercostal drain or in some cases may be applied to the surface of the visceral pleura under general anaesthesia using a thoracoscope.

As a rule these procedures produce pleural effusions that require drainage. Cerebral embolism has rarely been reported following the use of talc [211] and there have been fears about the possibility of subsequent mesothelioma due to potential contamination with asbestos, although this has not been borne out by experience [212,213]. Patients treated by chemical pleurodesis remain in hospital longer than those treated by intercostal tube drainage alone and the efficacy of the procedure in preventing recurrence has been questioned [214], although the balance of evidence is that it is more effective than tube thoracostomy alone but less so than surgical treatment [215,216].

Despite these disadvantages, chemical pleurodesis finds occasional application in the prevention of recurrent spontaneous pneumothorax, particularly in patients with serious respiratory impairment due to chronic lung disease, in whom more invasive surgery for pleurectomy or pleural abrasion might carry an unacceptable risk. Of the many substances that have been used, a solution of tetracycline hydrochloride (1–1.5 g in 50 mL of normal saline with 10 mL 1% lidocaine added) is currently favoured. Lidocaine is added to the solution to diminish the considerable pain that the procedure often produces. Once the lung has almost inflated and the pleural leak sealed or become minimal, the tetracycline is injected into the chest tube and flushed through with a further 50 mL saline. The tube is then clamped for the next 60–120 min while the patient is frequently repositioned (e.g. 5 min supine, prone, left and right lateral decubitus) so that the tetracycline comes into contact with all pleural surfaces, before the tube is unclamped for drainage (with or without suction) of any effusion that might have accumulated. Talc may be more effective than tetracycline, producing a vigorous granulomatous reaction but seemingly also producing greater pain and more prolonged fever [217]. Tetracycline has been claimed to be no less effective than silver nitrate, to cause less pain, diminished exudation and a shorter hospital stay [218]. Tetracycline pleurodesis has been shown to reduce ipsilateral recurrence rate significantly in a prospective controlled trial of patients with primary and secondary spontaneous pneu-

mothorax [215]. As a standard procedure for primary spontaneous pneumothorax, chemical pleurodesis does not currently find wide acceptance but continues to be used in some centres [216,218].

### **Parietal pleurectomy, pleural abrasion at thoracotomy and video-assisted thoracoscopic procedures**

A more major operative procedure is indicated if the lung fails to expand fully with tube drainage. Most leaks close within 2–3 days of insertion of a well-placed intercostal tube [219,220], failing which it is reasonable to consider a surgical opinion provided that the patient's general condition permits thoracotomy or thoracoscopy. A further delay of a few days is not important, so that an operation can proceed if still needed after about a week has elapsed from the insertion of the drain [199]. Patients with underlying lung disease are often left longer because of the increased risks that surgical intervention carries for this group. Prior to the advent of video-assisted thoracoscopic surgery (VATS), the standard procedure was parietal pleurectomy carried out through a posterolateral thoracotomy, in which the parietal pleura is stripped off the chest wall and upper mediastinum leaving a raw area that becomes adherent to the remaining visceral pleura [211]. Some surgeons prefer to produce a similar effect less radically by either limiting the procedure to the apex of the lung (apical pleurectomy) or alternatively by scarifying the parietal pleura with a dry gauze sponge or nylon pan scourer, a procedure known as pleural abrasion [221,222]. Both types of operation may include the excision, oversewing or stapling of any visible pleural blebs or bullae and, after either of these procedures, tube drainage is maintained for a few days to allow the visceral pleura to come into close apposition with the chest wall while adhesions form. Parietal pleurectomy is almost guaranteed to prevent recurrence (0.4%) and recurrence after pleural abrasion is also unlikely (2%) [38,223,224].

Although these 'open' procedures are still carried out in many centres, increasing use is being made of VATS. The indications for this intervention are broadly similar to those for the open procedures mentioned above and the temptation to refer patients routinely after a first episode of primary spontaneous pneumothorax should be resisted as the recurrence rate is only 20% or so. VATS usually entails the surgeon making three 1–2 cm incisions to establish a port for the thoracoscopic camera and one each for the grasping forceps and stapler. This compares with a thoracotomy wound, which although sometimes limited may extend anything up to 30 cm in length and is associated with greater morbidity and a longer hospital stay. VATS lends itself to the identification of leaking apical blebs in patients with recurrent or persistent primary spontaneous pneumothorax. These blebs can often be resected after placing a row of staples across their necks

**Fig. 44.15** Approximate sites of routine trocar positioning for video-assisted thoracoscopic surgery in pneumothorax, also demonstrating the stapled resection of an apical bleb. (a) The bleb is grasped; (b) the stapler is applied above a rim of normal lung tissue; (c) each staple application cuts between six rows of staples. (After Hazelrigg *et al.* [225].)

**Table 44.3** Indications for parietal pleurectomy or abrasion in spontaneous pneumothorax.

Failed tube drainage (persistent pneumothorax)
Ipsilateral recurrence (First or second)
Contralateral occurrence (First)
Bilateral simultaneous pneumothorax
Persistent pleural effusion
Initial episode life-threatening
Special risk groups e.g. aircrew, divers, etc.

[225] (Fig. 44.15). The bullae in patients with emphysema tend to merge with adjacent lung and are more difficult to deal with using VATS so that leaks are more frequent and other surgical techniques may need to be used, including formal thoracotomy. In addition to dealing with the leak, VATS may be used to establish a pleural symphysis by parietal pleurectomy, pleural abrasion or chemical pleurodesis. The recurrence rate is known to be higher if no leak can be identified and dealt with at thoracoscopy, in which case VATS pleurectomy may be a surer way to proceed [226]. There are reports of thoracoscopic ablation of pulmonary blebs and bullae by laser but in the setting of pneumothorax, the recurrence rate may be too high [226].

Parietal pleurectomy or abrasion may also be recommended after the first or second ipsilateral recurrence or following the first contralateral recurrence in order to avoid the future possibility of simultaneous bilateral spontaneous pneumothoraces [227]. Pleurectomy is indicated after the initial event for categories of patient in whom a recurrence would carry a special risk, such as aircrew, divers who refuse to stop diving, seafarers or other travellers to remote parts and those in whom the first pneumothorax was a life-threatening 'near miss' (Table 44.3). Surgical treatment is also indicated when pneumothorax is complicated by a large haemothorax, pleural effusion or

empyema that cannot be satisfactorily managed by aspiration or tube drainage alone. One potential problem with pleurectomy in a patient with pneumothorax is that the symphysis is so good that were a thoracotomy to be required in the future for some other reason, it would be made technically very difficult.

Patients with spontaneous pneumothorax secondary to cystic fibrosis may be managed with aspiration or tube thoracostomy. Cases of recurrence may be treated with chemical pleurodesis or thoracoscopically with ligation of bullae and limited pleural abrasion rather than with pleurectomy, unless it is quite certain that they are not candidates for future transplantation. It is sensible to discuss the management options for those patients with cystic fibrosis who are transplant candidates with the transplant centre concerned [59].

Spontaneous pneumothorax in pregnancy has rarely been reported. It can be treated with aspiration or tube drainage. Surgical treatment during pregnancy is sometimes necessary and there is no good evidence of teratogenesis, increased risk of abortion or premature labour following general anaesthesia. However, the risks from pneumothorax in pregnancy are also small [228] and

prolonged drainage with a flutter valve until after term has been reported as an alternative to surgical intervention [203,229].

Cases of catamenial pneumothorax thought to be associated with endometriosis may be treated medically by inducing a hypo-oestrogenic state with drugs such as danazol and analogues of gonadotrophin-releasing hormone, but are likely to produce improvement only while treatment is continued [230,231]. Endometriosis resolves at the menopause; however, apart from these pharmacological interventions, an earlier permanent cure requires bilateral oophorectomy, which may be appropriate (with hysterectomy) for women in their fifth decade. This may be followed with hormone replacement therapy without any recrudescence of pneumothorax since the problems in endometriosis seem to depend on cyclical variation in oestrogen level [232].

Sometimes patients with barotrauma due to diving accidents, in addition to possible pneumothorax and pneumomediastinum, may develop air embolism that should be treated by transport to the nearest centre with facilities for emergency hyperbaric oxygen therapy. This has the effect of reducing the volume of the air emboli physically according to Boyle's law, as well as accelerating absorption of gas by 'washing out' nitrogen from the body, thereby increasing the gradient for diffusion of nitrogen between the trapped gas and the tissues (see Fig. 44.11). The US Navy uses a protocol of rapid recompression with air to 600 kPa for 30 min, followed by 100% oxygen at 280 kPa [135].

## Complications

### Failure to re-expand

Failure to re-expand the lung by tube drainage may require the insertion of a second intercostal drain [9]. A persistent air leak requiring surgical intervention is reported in 4–14% of cases in whom tube drainage has been attempted [6,8,9,162]. These failures may be caused by multiple leaks in generalized emphysema or by adhesions preventing a bronchopleural fistula from closing. In such cases the treatment of choice is a surgical procedure to produce pleurodesis (see above), provided that the patient does not have severe respiratory impairment that would make the risk of thoracotomy or thoracoscopy unacceptable. Such high-risk patients usually have severe emphysema and with prolonged tube drainage the leak frequently seals off, although this may occasionally take weeks. However, an otherwise healthy subject should be offered a surgical procedure if tube drainage remains unsuccessful after 3–7 days [199,224,225]. Occasionally re-expansion of the lung is delayed by atelectasis resulting from retained secretions. This situation is treated by chest physiotherapy with an intercostal drain in place, although

rigid bronchoscopy may be required occasionally to suck out tenacious intrabronchial material and the passage of an endotracheal tube may be required in order to achieve full reflation.

Rarely a pneumothorax becomes chronic, with the result that the lung becomes surrounded and bound down by a thickened non-expansive layer of fibrin known as a pleural rind or peel. This is more likely to occur if there is an associated pleural effusion. A chronic pneumothorax is sometimes seen in cases of inactive tuberculosis that were treated with the now obsolete technique of artificial pneumothorax; in such cases the pleural rind is frequently heavily calcified [233] (Fig. 44.16). Surgical decortication of the pleura may be required to achieve re-expansion of the trapped lung, although this is seldom technically possible because of the dense nature of the adhesions.

### Recurrence

There is a tendency to overestimate the recurrence rate of spontaneous pneumothorax in the published series, many of which are retrospective and contain an unduly high proportion of patients referred to surgical units because of 'failed conservative treatment' or for the treatment of recurrence itself rather than for the primary event. In a study of 294 patients comprising all medically and surgically referred cases of spontaneous pneumothorax in a single institution, a recurrence rate of 16% was found in those treated for the first event either conservatively or with tube drainage [6]. Other series have reported a first recurrence rate of 16–50% [30,38,162,211,234,235]. At least half of those patients who experience a recurrence do so within 4 months of the initial episode [7,9,162]. Some series have recorded slightly lower recurrence rates following an intercostal tube as opposed to conservative treatment [162,236,237], although this experience is not universal [7]. After each recurrent spontaneous pneumothorax treated conservatively or by intercostal tube, the likelihood of a further episode increases; thus the chance of a third pneumothorax following the second has been found to be 40–64% [6,7,38] and the chance of a fourth pneumothorax following the third is reported to be 80% [238]. There is a risk of a subsequent contralateral spontaneous pneumothorax of 10–15% [9], although simultaneous bilateral pneumothoraces are unusual occurring in 1.3–2.5% of cases [38,162,163].

### Haemopneumothorax

Significant haemorrhage in association with spontaneous pneumothorax is uncommon but potentially fatal, early reports indicating a mortality rate approaching 20% [211,239]. It was reported in 2.3% of one recent surgical series with no mortality [240]. The source of blood loss is usually the chest wall side of a vascularized adhesion that

**Fig. 44.16** Chronic bilateral fibrothoraces, with heavily calcified visceral pleura, in a patient previously treated for tuberculosis with artificial pneumothorax.

is torn apart as the pneumothorax develops [163]; it is of historical interest that this was also a recognized complication following the induction of artificial pneumothoraces when these were used in the treatment of pulmonary tuberculosis [241]. Blood loss may produce shock with sweating, nausea and syncope. Treatment comprises prompt replacement of blood; if blood loss is excessive, early surgical intervention to achieve haemostasis is necessary [240]. Adequate aspiration or drainage is all that is required for smaller amounts of blood. Thoracoscopy or thoracotomy may be required if the organization of substantial clot prevents expansion of the lung, although smaller amounts may gradually reabsorb without intervention.

### **Pyopneumothorax**

Pyogenic infection of the pleural space was reported in less than 1% of cases of spontaneous pneumothorax in one early Scottish series and was also found to be surprisingly uncommon following penetrating trauma to the chest wall [104,162]. This does not apply to countries with less well-developed healthcare facilities and those with a high prevalence of tuberculosis. The infecting organisms may enter the pneumothorax space as a result of suppurative pneumonia or rupture of a lung abscess or may be introduced at pleural aspiration, during intercostal tube

drainage or at thoracotomy. Treatment comprises prompt and adequate drainage by aspiration or intercostal tube and appropriate antibiotic therapy. When these measures fail surgical intervention is indicated (see Chapter 14).

### **Respiratory failure**

This is unlikely to occur in the absence of pre-existing respiratory disease other than when a tension pneumothorax is present. It is characterized by hypoxia, hypercapnia and respiratory acidosis and treatment involves urgent re-expansion of the deflated lung and controlled oxygen therapy according to arterial blood gas analysis.

### **Re-expansion pulmonary oedema**

Unilateral pulmonary oedema is an unusual but well-documented complication that may follow the re-expansion of a completely collapsed lung, not only after the treatment of pneumothorax [242] but also sometimes following the aspiration of a large pleural effusion or after the relief of bronchial obstruction, as in the case of the withdrawal of a misplaced endotracheal tube. It is thought to be more likely to occur if the pneumothorax has been present for several days and if re-expansion is rapid, as may occur if suction has been applied [243,244], although

it can occur when collapse of the lung has been present for only a few hours. Radiographic evidence of unilateral pulmonary oedema on the side of the treated pneumothorax was found in 0.9% of a retrospective series of 320 episodes of spontaneous pneumothorax collected over an 8-year period and treated with intercostal tube drainage [245]. The mechanisms are open to conjecture but possibilities include increased pulmonary capillary permeability resulting from raised transpulmonary negative pressures acting on lung tissue, whose elastic recoil has been increased by loss of surfactant; alternatively, there may be pulmonary microvascular injury by oxygen free radicals or other substances produced as a result of hypoxic lung injury occurring during the period of collapse [246,247]. Curiously, contralateral or bilateral pulmonary oedema has also been described on rare occasions [248,249].

This complication may be asymptomatic, being detected on a routine film, or it may result in cough and dyspnoea [245]. Although unusual, marked respiratory distress with severe hypotension and death have occasionally been reported [245,248,250]. The radiographic findings are those of unilateral pulmonary oedema and are non-specific. Treatment is by correction of hypoxaemia and hypovolaemia if present and with inotropic support where appropriate. Mechanical ventilation may sometimes be necessary [251].

### Other complications of management

Some complications that may arise as a direct result of the placement of intercostal tube drains have already been mentioned. The most serious are haemorrhagic. Bleeding may occur as a result of injury to a vascular structure, usually one of the intercostal vessels, less commonly the internal mammary artery or another major vessel. Elderly patients may have more tortuous intercostal arteries than younger people and may therefore be more vulnerable [252]. Other serious structural injury is only likely to arise as a result of the misplacement or overpenetration of a trocar. Trauma cases who are dealt with as emergencies are particularly vulnerable since their thoracic cavities may contain abdominal viscera as a result of diaphragmatic rupture and the normal mediastinal structures may also be displaced. The liver, spleen, bowel, major vessels or even the heart may be inadvertently punctured during tube placement so that various advanced trauma life support guidelines recommend that intercostal drains should be inserted without a trocar in such cases [253,254]. Massive haemorrhage is best dealt with by clamping the tube in the hope that this tamponades the flow, by replacing lost volume as rapidly as possible and by requesting thoracic surgical help immediately. Smaller bleeds thought to come from intercostal vessels have been tamponaded by replacing the chest tube with a large Foley urinary catheter and applying traction to its overinflated

balloon, although experience with this technique is not widespread [255]. Misplaced tubes have been known to injure the brachial plexus and occasionally an apical drain may abut the sympathetic chain producing neuropraxia with Horner's syndrome [256]. Sometimes a track may develop between the outside of a drain and the chest wall so that the air is drawn into the pleural cavity on inspiration, thereby defeating the purpose of the exercise and necessitating removal and resiting or an alternative surgical approach, depending upon the circumstances.

Many of these problems can be prevented by scrupulous attention to detail as outlined in the section on intercostal tube drainage. It is notable that a retrospective North American study conducted to determine the complication rate of tube thoracostomy found a strikingly lower complication rate when tubes were placed by a surgeon rather than an emergency physician, implying that additional training might be important [257].

## Pneumomediastinum

Air in the mediastinal tissues is referred to as pneumomediastinum or mediastinal emphysema. Although the condition of pneumomediastinum has been recognized for over a century [258], the first detailed accounts are credited to Hamman [167,259]. A working classification based on cause, similar to that applied to pneumothorax, is recommended (Fig. 44.17). Thus any pneumomediastinum occurring in the absence of trauma may be described as spontaneous. The term 'primary spontaneous pneumomediastinum' is used in the absence of any demonstrable predisposing disease and 'secondary spontaneous pneumomediastinum' where the leakage of air has arisen as a result of a recognizable coexisting structural abnormality, usually in the lungs or mediastinum; thus any of the causes of secondary spontaneous pneumothorax may also result in secondary spontaneous pneumomediastinum.

### Aetiology

Pneumomediastinum may arise following alveolar rupture, in which case air tracks along interstitial and vascular supporting tissues (see Fig. 44.4) until it reaches the mediastinum [260]. Air may also be released directly into

Fig. 44.17 Classification of pneumomediastinum.

the mediastinum following tracheal, bronchial or oesophageal rupture in association with chest trauma, local disease or endoscopic examination [261]. The initiating event may be a rise in intrathoracic pressure such as occurs with coughing, straining or during positive-pressure ventilation. In this regard the condition has been recorded in upper respiratory tract infection, asthma, bronchitis, whooping cough, obstructive laryngitis, choking on a foreign body and with various forms of physical exertion including childbirth [262–272]. Frequently, however, no precipitating cause is found as was emphasized in early reports [259].

Alveolar rupture may also follow the decompression of intrathoracic gas, as may occur in a surfacing diver or in aircrew subjected to sudden accidental cabin decompression at high altitude (p. 1187). The surgical dilatation of an oesophageal stricture is a frequent cause of rupture of this viscus, particularly if the lumen is blocked by carcinoma. Violent vomiting may sometimes give rise to a vertical tear in the lower 8 cm of the oesophagus posterolaterally [273]. Air is occasionally drawn into the fascial planes of the mediastinum from wounds in the neck, including tracheostomy and surgical procedures in the mouth, pharynx and upper gastrointestinal tract [274]. Gas in the mediastinum may also be introduced by high-speed air turbine dental drills [275,276] and even by attempting to uncup a carbonated beverage bottle with the teeth [277]. Strenuous physical exertion coupled with retching that may not be recalled could be the explanation for occasional reports of pneumomediastinum occurring in association with the recreational use of 3,4-methylenedioxymethamphetamine ('ecstasy'), typically taken at discothèques and 'raves' [278]. Rarely gas may enter the thorax from a ruptured viscus in the abdomen, ascending retroperitoneally alongside the oesophagus and aorta.

### Clinical features

Primary spontaneous pneumomediastinum occurs predominantly in young previously healthy males aged 15–30 years [264,279]. All grades of clinical severity exist and the condition is almost certainly underdiagnosed in milder cases. The most consistent symptom is central chest pain, produced as a result of air spreading about the mediastinal tissues [263]. It may be slight or severe, mimicking that of myocardial infarction or pericarditis and radiating to the shoulders, arms and neck. Any movement that disturbs the mediastinal structures, such as deep breathing, turning or swallowing, may aggravate the pain and the patient may obtain relief by leaning forwards in the sitting position and by breathing shallowly [280]. Pain in the neck may be accompanied by dysphagia, which may be the principal complaint [264]. There may be a change in the quality of the voice [265]. Surgical emphysema is frequently palpable in the neck and may be more

widespread, involving the face, chest or arms particularly if the channel through which air has entered the mediastinum remains patent or if the patient is being ventilated mechanically. Pulsus paradoxus has been described in the absence of asthma [264]. The normal area of cardiac dullness to percussion may be diminished and on auscultation the heart sounds may be indistinct. Hamman's sign is variously described as a crepitous, crackling or crunching sound that may be heard with the stethoscope to be synchronous with systole. It is usually maximal at the left sternal edge with the patient sitting forwards or lying in the left lateral decubitus position. This sign is present in about 50% of cases of pneumomediastinum and is occasionally noticed by the patient or even by a casual observer. It is not entirely specific for pneumomediastinum, having been described in left-sided pneumothorax [166], bullous emphysema of the lingula, distension of the lower oesophagus or stomach by air, and pneumoperitoneum with a high left hemidiaphragm [281]. On rare occasions sufficient air under tension surrounds the heart to cause cardiac tamponade, with breathlessness, cyanosis and hypotension. When secondary spontaneous or traumatic pneumomediastinum occurs, the symptoms and signs of associated disease such as pneumothorax or oesophageal rupture are frequently present. The latter condition is often indicated by the presence of fever and a pleural effusion or empyema, the source of which may be demonstrated by asking the patient to swallow dye such as methylene blue, which can then be shown to be present in an aspirate of pleural fluid. In lower oesophageal rupture the upper part of the abdomen may be rigid, suggesting a perforated gastric or duodenal ulcer. There may be the symptoms and signs of an associated pneumothorax.

### Radiographic features

It is usually the chest radiograph that provides indisputable diagnostic evidence of pneumomediastinum (Fig. 44.18). Free mediastinal air is usually seen as sharp lines of increased lucency that enhance the mediastinal viscera, run along and outline one or both of the cardiac borders and extend to the superior mediastinum, which may appear widened [172]. A continuous diaphragmatic 'shadow' has also been described [282]. If posteroanterior views only are taken, then about 50% of cases that would otherwise be detected with a routine lateral view may be missed [283]. This projection may show a collection of air lying between the sternum and heart. In the neck posteroanterior and lateral views may show air tracking along the fascial planes. In cases of doubt, mediastinal air may be evident using either echocardiography or CT [261,278]. A water-soluble, non-ionic (e.g. Iopamidol, Gastrografin) contrast examination may be helpful where oesophageal perforation is suspected.

**Fig. 44.18** Mediastinal and subcutaneous air due to instrumental perforation of pyriform fossa.

### Diagnosis

Failure to diagnose pneumomediastinum usually results from the omission of this possibility in the differential diagnosis when a subject presents with central chest pain. Difficulty may arise when the air leak has been small, with the result that the usual physical signs are absent; in this case, free air must be assiduously sought on the radiographs. Myocardial infarction is usually easily distinguishable by serial changes on the ECG and a rise in cardiac enzyme levels. However, caution should be exercised in interpreting the ECG since ST and T wave changes have been described in both pneumothorax and pneumomediastinum [175,263,284].

### Management

Primary spontaneous pneumomediastinum seldom requires any treatment other than reassurance, observation and simple analgesia should the pain require it. The

administration of high concentrations of oxygen may be beneficial in the rare situation in which trapped air in the mediastinum is limiting diastolic filling of the heart. This causes nitrogen to be washed out of the body, thereby increasing the gradient of  $P_{N_2}$  between the pneumomediastinum space and the tissues so that the trapped air is more rapidly absorbed (see Fig. 44.11) [285].

When a pneumomediastinum is secondary to another disease process or to trauma, therapeutic efforts are directed to the primary condition since it is usually of much greater clinical importance. Coexisting pneumothorax should be treated on its own merits (see above) and should be searched for, particularly when pneumomediastinum develops in patients who are being mechanically ventilated. When tracheobronchial or oesophageal ruptures are suspected, endoscopic examination or contrast swallow may be required. Major perforations, especially if they have resulted from trauma, usually require operative treatment. Minor oesophageal tears, which may have arisen from endoscopy itself, are frequently managed conservatively with antibiotics and drainage of any coexisting pleural effusion. Although air may have entered the mediastinum by purely physical means, the finding of gas in

these tissues should certainly alert the physician to the possibility of mediastinitis from anaerobic organisms that may have been introduced from adjacent areas.

The majority of cases of primary spontaneous pneumothorax are absorbed within 1 week. Recurrence is unusual but has been described [260,263].

# CHEST WALL AND NEUROMUSCULAR DISORDERS

ANTHONY SEATON

## Congenital abnormalities of the chest wall

### Rib abnormalities

Bifid ribs are common, particularly in the upper six ribs, and if not appreciated on the chest radiograph may give rise to confusion in interpretation [1]. Fused and absent ribs may also occur but are only of radiological interest. An asymmetrical congenital deformity has been described in adolescent patients in whom the ribs and costal cartilages on the right side are deeply depressed and the sternum rotated to the right [2]. Reconstructive surgery is possible.

Cervical ribs occur in 0.5% of the population, usually arising from the seventh cervical vertebra; they may vary greatly in size and shape, and are bilateral in 80% of cases [3,4] (Fig. 45.1). They are usually asymptomatic but may give rise to the thoracic outlet syndrome due to compression of subclavian vessels or nerves in the root of the neck. Symptoms due to compression are more prevalent in females and more common on the left [3]. The production of symptoms bears no relation to the size of the rib; a small cervical rib with a fibrous attachment may cause severe symptoms whereas a large cervical rib may be asymptomatic. The thoracic outlet syndrome has been described following correction of scoliosis in a patient with cervical ribs [5].

Neurological symptoms of cervical ribs commonly consist of pain and weakness of the arm with paraesthesiae of the fingers. Atrophy of the intrinsic muscles of the hand may occur [6,7]. Vascular symptoms may mimic Raynaud's phenomenon, and emboli from a thrombosed subclavian artery may cause fingertip gangrene [6,7]. Neurological complications need not require resection of the offending rib since the majority respond to shoulder girdle strengthening exercises and the avoidance of heavy loads. However, vascular complications may require arteriographic investigation and treatment depends on the findings, ranging from simple rib resection to arterial

reconstructive surgery plus embolectomy or thrombectomy [3,4].

### Jointed xiphoid process

A jointed xiphoid process may masquerade as an upper abdominal mass but may be readily recognized on a lateral chest film or by ultrasound examination, thus preventing unnecessary operation [8].

### Pectus carinatum or pigeon chest

In this condition the sternum is prominent, forming an anterior ridge like the keel of a ship with the ribs falling away steeply on either side, sometimes with a vertical groove on each side of the sternum [9,10]. It may be associated with other congenital anomalies, especially cardiac lesions and coarctation of the aorta [11].

### Aetiology

Pectus carinatum may result from obliteration of all the sternal sutures at an early age, possibly due to inadequate segmentation during fetal life, with a resulting synostosis [9]. An alternative explanation, which has been confirmed at postmortem, is that the deformity results from malattachment of the anterior portion of the diaphragm to the posterior portion of the rectus sheath rather than to the xiphoid process, with consequent distorting mechanical effects [12].

### Management

There is no associated functional defect and correction is not normally indicated. However, corrective procedures for both types of pectus carinatum have been described and may be required for cosmetic reasons [10,13]. Such patients are almost invariably happier with the large scar than with the deformity, though this effect of the operation

Fig. 45.1 Bilateral cervical ribs.

should be discussed with them before referral to a thoracic surgeon.

### **Pectus excavatum or funnel chest**

In this condition the manubrium is normal but the body of the sternum is angled backwards towards the spine from the manubriosternal joint downwards with maximum recession at the xiphoid, below which the costal margin bends forwards. The condition is usually symmetrical but occasionally the sternal recession may be greater on one side than the other. As with pectus carinatum, there may be associated congenital anomalies and Marfan's syndrome may be present.

### **Aetiology**

Pectus excavatum probably results from an imbalance of forces counteracting the inward pull of the diaphragm on the xiphisternum. Biopsies have shown that the anterior portion of the diaphragm is replaced by fibrous tissue. In the normal person the muscle in this region contracts on inspiration and its attachments to the lower chest wall on either side of the xiphisternum and lower sternum prevent these being dragged backwards as the diaphragm descends. When this muscle is lacking, the unopposed action of the posterior diaphragmatic muscle displaces the sternum and xiphisternum backwards as the diaphragm descends [12]. This movement occurs in affected newborn infants only on inspiration but after the age of 3 months the deformity progresses, with resulting secondary changes in the sternum and costal cartilages.

It has been suggested that an additional factor is a congenital laxity of the pericardium that allows the heart to fall to the left, removing its support from the sternum [14], and it has been recommended therefore that at operation the pericardial sac should be sutured into a central position. It has also been suggested that upper airway obstruction, whether due to enlarged tonsils and adenoids or segmental bronchomalacia, appears to predispose to

pectus excavatum, which may resolve if the obstruction is treated early enough [15–17]. An association between pulmonary sequestration and pectus excavatum has been described [18].

There is said to be a hereditary tendency to the development of pectus excavatum but no sex linkage. The condition was reported in 2.2% of boys and 2.5% of girls in a German series [19].

### **Pulmonary function**

Minor decreases in vital capacity (VC), total lung capacity (TLC) and maximal ventilation volume (MVV) have been reported in pectus excavatum with normal or increased residual volume (RV) and a normal forced expiratory volume in 1 s ( $FEV_1$ ) [20–22]. Even in the presence of normal pulmonary mechanics and lung volumes, it may be possible to demonstrate abnormal findings during exercise in symptomatic patients. Of eight such patients with exercise limitation, five demonstrated a diminished tidal volume expressed as percentage vital capacity at maximal exercise and had excessive oxygen uptake at higher loads consistent with an increased work of breathing [23].

### **Clinical features**

In most cases the main symptom due to the deformity is the embarrassment caused to the patient by the deep furrow in the chest. In surgical series, however, where selection by degree of severity has occurred, patients are recorded with severe symptoms of dyspnoea, precordial pain, syncope on moderate exertion, palpitations and recurrent lung infections [12]. Incapacitating supraventricular tachycardia provoked by exercise and cured by surgery has been reported [24].

In children with pectus excavatum the majority have auscultatory findings suggestive of cardiac disease, with murmurs mimicking those of pulmonary stenosis or a small atrial septal defect [25]. These murmurs are

presumed to be due to the resultant cardiac displacement. It has been reported that a cartilaginous horn from the inner surface of the xiphoid may impinge on the heart with resultant ECG changes and/or angina and that this may be cured by operation [26]. The ECG may show persistence of the juvenile pattern, with T inversion in the right precordial leads, incomplete right bundle branch block and right axis deviation. Because of cardiac rotation there may be P-wave inversion in  $V_1$  and a QR pattern [27].

### Radiology

On the posteroanterior chest film the heart is often displaced to the left and anterior ribs may show marked obliquity (Fig. 45.2). The depressed sternum is obvious on the lateral chest film and various indices for assessing the severity of disease and response to surgery using this film have been described [28]. Paradoxical cardiac enlargement during inspiration in children with pectus excavatum has been reported and is due to reduction of the anteroposterior diameter of the thorax caused by diaphragmatic descent [29].

### Treatment

Surgery is rarely required because of cardiorespiratory symptoms, although these may occur in a minority and be disabling as described above. More often, surgical repair is sought for cosmetic reasons. It is usual to resect the deformed costal cartilages and perform an osteotomy of the anterior table of the sternum, providing internal fixation by the use of a bar that passes anterior to the rib cage but behind the sternum. Early cosmetic and functional results are usually good, and most recent reports indicate a satisfactory long-term result [30,31]. Unsatisfactory results have been recorded in patients with severe and asymmetrical deformities and with Marfan's syndrome [31]. Lung function is likely to deteriorate rather than improve shortly after surgery, thereafter sometimes recovering to its original level [22,32,33]. Nevertheless, the majority of patients are happy with the cosmetic results.

### Straight back syndrome

The straight back syndrome is a presumed congenital abnormality in which there is absence of the physiological dorsal kyphosis of the spine as determined on a lateral chest radiograph.

### Clinical features

Presumably because of compression of the heart and great vessels between the spine and sternum, with resultant

compression of the pulmonary outflow tract, a pulmonary ejection systolic murmur is not infrequently found [34,35]. A palpable left parasternal systolic impulse may be present and exaggerated respiratory splitting of the second heart sound may be heard. An ECG may show an rSr pattern in  $V_1$ . These subjects are reported not to differ from controls in work capacity, FEV<sub>1</sub>, diffusing capacity or arterial blood gas tensions, although total lung capacity may be reduced [36].

### Radiology

The lateral chest radiograph suggests the diagnosis, showing loss of dorsal kyphosis and reduced anteroposterior diameter of the chest. On the posteroanterior film the pulmonary arteries may be prominent and the heart shadow is often displaced to the left, sometimes with a pancake configuration [36].

### Poland's syndrome

Poland's syndrome consists of syndactyly plus ipsilateral absence of the pectoralis major muscle [37]. This results in hypoplasia of the ribs on the affected side and hypertranslucency of the lung on the posteroanterior chest radiograph.

### Sternal abnormalities

An unusually wide sternum, with the suggested name eury sternum, and sternal foramina visible on chest radiography and bone scans have been described [38]. They are of no clinical significance.

### Congenital kyphoscoliosis

A minority of cases of kyphoscoliosis are congenital in origin and these are considered later in this chapter.

## Acquired abnormalities of the chest wall

### Fractures [39]

#### Traumatic fractures

Trauma to the chest wall may be inadvertent and unnoticed by the patient, particularly when under the influence of alcohol, anaesthetics or in a coma, and may sometimes give rise to problems in differential diagnosis. A rib fracture should be suspected if there is acute local rib tenderness at the site of pain of recent onset or if pain occurs on springing the ribs. Palpable or audible crepitus may be found at the site. If penetration of the parietal and visceral pleura occurs, there may be signs of pneumothorax and

(a)

(b)

**Fig. 45.2** Posteroanterior (a) and lateral (b) chest films of patient with pectus excavatum. Slight apparent enlargement at the left hilum is due to compression by the depressed sternum.

subcutaneous emphysema. The presence of multiple healed rib fractures on a chest film should call attention to the possibility of alcohol abuse.

### Fatigue fractures

These may occur in the first or second ribs, most commonly in young soldiers carrying heavy rucksacks or rifles. Often there is little pain but the fracture may result in fibrous union or a residual cyst [40].

### Cough fractures

Cough fractures are common and most frequently seen in patients with severe chronic airways obstruction, usually due to chronic bronchitis and emphysema, and in whooping cough. Predisposing factors include corticosteroid therapy or senile osteoporosis and osteomalacia. Cough fractures are associated with sudden onset of pain while coughing, the subsequent pain usually being worse on coughing than breathing. The local signs are as for a traumatic fracture, although pneumothorax is not usually seen. They are located most frequently in the mid-axillary line.

### Pathological fractures

Pathological fractures may occur with rib metastasis or osteolytic primary tumour of rib such as myeloma.

### Radiology

Unless there is displacement of a fracture it may not be visible on the radiograph even in the acute stage, and radiologically visible callus formation does not occur for several weeks. The diagnosis is therefore frequently clinical. Pneumothorax and/or subcutaneous emphysema may be seen with traumatic lesions, while the primary lesion may be visible in the case of pathological fractures. Sometimes the film may show linear shadows 2–3 cm long underlying a traumatically fractured rib, possibly due to bruising of the lung [40].

### Treatment

Treatment with adequate analgesia is usually all that is required, although occasionally it may be necessary to infiltrate with local anaesthesia. Lower respiratory tract infection, particularly on the affected side, may develop in patients with chronic airways obstruction and require intervention with antibiotics. Chest wall strapping is contraindicated since it predisposes to the same complication.

## Scoliosis

Scoliosis is defined as a lateral curvature of the spine and is associated with rotation of the spine and viscera adjacent to it. It may be (but is usually not) accompanied by kyphosis [41].

### Aetiology

An abbreviated aetiological classification is shown in Table 45.1 [41]. Non-structural causes include the well-known sciatic scoliosis, a temporary scoliosis occasioned by irritation of sciatic nerve roots. Structural causes are identified by the persistence of fixed rotation of the spine on forward bending. The majority of cases of scoliosis nowadays are idiopathic in origin. Idiopathic scoliosis may be seen at all ages during growth and at all spinal

sites, although thoracic scoliosis to the right is the most common presentation [42,43]. The condition is more prevalent in girls. The higher in the spine the structural curve, the worse the prognosis. Prognosis is also a function of the angle of curvature, which is measured as shown in Fig. 45.3; lines are drawn parallel to the upper border of the upper vertebral body and to the lower border of the lowest vertebra of the structural curve. Perpendiculars are then erected from these lines to cross each other, the angle between the perpendiculars being the angle of curvature or Cobb's angle [44].

Neuropathic and myopathic conditions, of which poliomyelitis is the most common example, are usually associated with a worse prognosis for a given degree of curvature as a result of the associated muscle weakness and consequent ventilatory problems. Scoliosis due to poliomyelitis usually appears within 2 years of infection.

### Pathology

In scoliosis the total lung volume is reduced and the lungs differ in size, with distortion of lobar shapes due to the deformity [45]. Alveolar size may vary; if scoliosis has been present from an early age, alveolar numbers per acinus may correspond to that developmental stage [46]. In severe scoliosis progressing to cor pulmonale, the pulmonary changes of marked vascular medial hypertrophy are indistinguishable from the changes seen in other causes of cor pulmonale [47].

### Physiology

Because of the reduction in height occasioned by the spinal deformity, it is conventional to calculate predicted values for lung function in scoliosis on the basis of arm span measurements, arm span correlating closely with height in normal subjects [48]. Lung volumes are reduced, with a restrictive pattern even in asymptomatic adolescents with scoliosis. VC, TLC, MVV, functional residual capacity (FRC) and peak expiratory flow (PEF) and are all reduced and there is a direct relationship between the angle of curvature and the degree of reduction of these indices [49–54]. The higher the curve in the dorsal spine, the more severe its effect on function. RV may be maintained, resulting in an increased RV/TLC ratio [50]. The FEV<sub>1</sub>/forced vital capacity (FVC) ratio is normal unless obstructive disease such as asthma supervenes [49]. Diffusing capacity for carbon monoxide (DLCO) is reduced in proportion to the reduction in lung volumes, giving normal values for Kco [49,52,53,55]. In paralytic scoliosis, similar changes are seen in lung volumes; however, for a given angle of curvature diminution of lung volumes is more severe [56] and the correlation of lung volume changes with Cobb's angle less clearly seen, reflecting the contribution of affected muscle to the disorder of lung function.

Lung compliance in scoliosis is commonly low, perhaps reflecting occurrence of small airway collapse due to inability to take a deep breath or a sigh [51,57,58]. This decreased compliance is also most pronounced in those with muscle weakness and can be increased by positive-pressure ventilation [59,60]. In scoliotic patients with impaired cardiorespiratory response to exercise, maximal oxygen uptake is reduced compared with age- and sex-matched normals, and ventilation at a given oxygen uptake is 20% higher than in normal subjects [61]. Exercise tolerance is thus limited in these patients by ventilatory factors.

Regional perfusion and ventilation are often normal in patients with scoliosis studied with xenon-133 techniques, although reduction in ventilation and perfusion at the lung bases does occur to a greater extent with increasing angle of curvature and age [55,62–64]. Pao<sub>2</sub> is diminished even in asymptomatic adolescents with scoliosis, and with severe disease carbon dioxide retention occurs [64]. As a consequence of increasing hypoxia, pulmonary artery hypertension occurs, the pressure being inversely proportional to Pao<sub>2</sub> [65,66]. In patients with severe scoliosis (with an angle  $\geq 100^\circ$ ), severe desaturation may occur during sleep with episodes of central or obstructive apnoea and hypopnoea, particularly during REM sleep [67,68]. The occurrence of carbon dioxide retention raises the possibility of defective chemical control of ventilation. Diminished ventilatory responses to carbon dioxide have been demonstrated in patients with both the idiopathic

and paralytic types of scoliosis, where the mechanical deformity has been the presumed explanation [51,55].

Finally, in patients with scoliosis of whatever degree, diminution in the maximum inspiratory and maximum transdiaphragmatic pressures has been recorded, suggesting that inspiratory muscle function is impaired, as a consequence of either a primary muscular problem or defective mechanical coupling between the inspiratory muscles and the rib cage [57,69].

### Clinical features

It is unusual for patients with mild scoliosis to have respiratory symptoms. However, physiological studies of such patients have shown reduced muscularity and work capacity and an excessive cardiovascular response to exercise, suggesting cardiovascular unfitness [70]. Daytime somnolence may indicate the presence of nocturnal desaturation, a common occurrence as the patient's condition deteriorates. In more severe cases exertional dyspnoea may occur and is due to the restriction of lung volumes that these patients have. Airways obstruction, which is often reversible, may also develop. In patients with a mid or high thoracic curve greater than about 100°, progression to pulmonary hypertension and right ventricular failure often occurs in the fourth decade, usually presenting with increasing dyspnoea; syncope, angina or sudden death may occur. Death most commonly occurs as a result of respiratory failure or cardiac disease, and the risks are highest in juvenile scoliosis and scoliosis after polio [71]. In severe scoliosis, acute respiratory failure may be precipitated by respiratory tract infection, and deterioration in these patients may be more rapid and severe than in patients with end-stage chronic bronchitis and emphysema for example. This necessitates careful attention to antibiotics, oxygen and physiotherapy with recourse to assisted ventilation, which is employed if the future prognosis warrants such intervention.

### Treatment

#### *Surgery*

Although surgical intervention, for example by spinal fusion, may ameliorate the angle of curvature and halt the progression of scoliosis, remarkably little benefit has been documented in terms of pulmonary function tests apart from an improvement in submaximal exercise ventilation [72].

#### *Medical treatment*

Following the initial episode of acute respiratory failure in severe scoliosis, the rate of deterioration of FEV<sub>1</sub> has been shown to be much slower than in patients with chronic

bronchitis and emphysema, and prolonged survival is possible after such an initial event [73]. Long-term domiciliary oxygen therapy may be useful as initial management of respiratory failure [74], although most patients ultimately need some form of assisted ventilation (see Chapter 58). In patients with late-onset respiratory failure in paralytic poliomyelitis, it has been shown that improvised long-term intermittent positive-pressure ventilation not only improves the patient's sense of well-being but also arterial blood gas tensions [75]. It is now apparent that home ventilation is of substantial benefit to patients with severe scoliosis. The most usual starting regimen is nasal intermittent positive-pressure ventilation, which has been shown to reduce admissions to hospital and to result in improvements in blood gases [76,77]. Alternative means of support for patients with life-threatening hypoventilation include tank respirators or cuirass shells. The latter can be individually moulded and tailored for each patient's deformity, and nocturnal ventilator support with such a system produces dramatic improvement in daytime blood gas tensions and also reduces the need for hospitalization [78–81]. Less satisfactory for the patient, but equally effective, is nocturnal ventilation via a permanent tracheostomy [82]. The effectiveness of nocturnal assisted ventilation is probably due to abolition of the more severely reduced blood gas tensions found at night [67,68]. Respiratory muscles that are rested at night and prevented from becoming fatigued are more capable of sustaining satisfactory ventilation and blood gas tensions by day.

Needless to say, appropriate diuretic therapy is indicated where right heart failure is present, and individual patients may also have superadded obstructive ventilatory defects that respond to bronchodilator therapy. Infective episodes are treated along routine lines.

### Ankylosing spondylitis

#### *Aetiology*

The aetiology of ankylosing spondylitis is unknown but the strong association with HLA-B27 is now well recognized, and individuals homozygous for HLA-B27 may have more severe disease [83–88]. Blood donor studies have suggested a disease prevalence of 1–2% depending on the frequency of B27 in the population [89]. The disease is much commoner in young adult males than in females.

#### *Pathophysiology*

Fixation of the thoracic cage occurs in ankylosing spondylitis as a result of ankylosis of costotransverse and costovertebral joints. Sternomanubrial and sternoclavicular joints may also be affected [90]. In one study, 70% of patients had chest expansion of less than 5 cm when first

seen [90]. In severe disease a restrictive pattern of abnormality is seen, with a reduction in VC due to reduced inspiratory capacity and a reduction in TLC [90,91]. RV and FRC are normal or slightly increased [90,92]. Gas exchange is normal [92]. As might be expected, thoracic and total respiratory compliance are decreased but lung compliance is normal [93]. Xenon-133 studies have shown normal perfusion but reduced apical ventilation in patients, although later studies suggested that apical underventilation is only seen in the presence of fibrosis [94,95].

### Clinical features

Despite the functional abnormalities described, respiratory disability is uncommon in ankylosing spondylitis, although dyspnoea on exertion may occur. In most cases the diaphragm appears to compensate more than adequately for the restriction of thoracic wall movement. However, an occasional patient may develop respiratory failure due to very extensive chest wall disease. Chest pain is not uncommon and may be diffuse and prolonged or short and stabbing in character. It is usually located in the lower anterior chest and there may be an associated island of pain higher up posteriorly, suggesting that the phenomenon is one of radiating intercostal pain from posterior spinal joints [96].

In 1972, Davies [97] described seven patients with ankylosing spondylitis and apical lung fibrosis. Found late in the history of the disease, the fibrosis begins as consolidation that may extend to upper and mid zones bilaterally (Fig. 45.4) and may subsequently cavitate with bulla formation. Aspergillomas may form in the cavities or bullae with attendant symptoms of cough and/or haemoptysis (see Chapter 21). Transient pleural effusions have also been reported in ankylosing spondylitis but such pleuropulmonary manifestations are rare, occurring in only 1.3% of 2080 patients in one study [98].

Adenocarcinoma has been reported in association with the apical fibrosis of ankylosing spondylitis [99]. There has also been a further report of pathology suggestive of bronchocentric granulomatosis associated with *Aspergillus* colonization [100]. Other rare complications of ankylosing spondylitis that have been reported include acute respiratory failure from extrathoracic airway obstruction due to ankylosis of the cricoarytenoid joints [101] and amyloidosis of the lungs [102].

### Treatment

Chest pain usually responds to minor analgesics. No other treatment is usually required or indicated apart from the management of mycetoma complications. In occa-

**Fig. 45.4** Bilateral upper lobe fibrosis with disappearance of the main pulmonary arteries into the fibrotic lesions. There is also cavitation due to secondary bronchiectasis in the right upper lobe and bilateral basal pleural thickening. The patient had severe ankylosing spondylitis.

sional patients with severe disease, surgical attempts have been made to mobilize the chest by resection of the posterior parts of several ribs or by other procedures, some of which appear to have improved respiratory function [103].

### **Slipping rib syndrome**

#### **Clinical features**

The slipping rib (syn. rib tip or clicking rib) syndrome [39,104,105] consists of intercostal radicular pain that may be episodic or continuous, mild or severe, and which is exacerbated by movement, as on rising from a chair. The pain is due to irritation of the intercostal nerve anteriorly by an adjacent rib or costal cartilage, and most commonly involves the eighth, ninth and tenth ribs, more frequently on the right than the left. The condition is more common in women than men, with an average age at onset of 29. The symptom may be reproduced by moving the affected rib, when a clicking or grating sound may be heard.

#### **Treatment**

The condition may respond to local injection of anaesthetics or steroids but if severe may require subperiosteal excision of the affected rib and costal cartilage. At operation the affected rib is found to be unduly mobile and to slip under the superior adjacent rib. The results of operation are good, with 82% of patients being pain-free at 7 days [106].

### **Sternocostoclavicular hyperostosis**

#### **Clinical features**

Kohler and colleagues [107] described five patients presenting between the ages of 44 and 46 years with an 11–34 year history of a persistent pulling pain in the sternum, clavicles and upper ribs that was exacerbated by cold and dampness. Others have reported episodes of painful hot swelling at the same sites [108–110]. Club-like symmetrical enlargement of the clavicles was present, and in two patients venous congestion of the upper half of the body was seen. In these patients, atrophy of the shoulder girdle and occlusion of the subclavian vein, which was sometimes bilateral, appeared to occur for mechanical reasons [107,110]. The erythrocyte sedimentation rate (ESR) was markedly elevated.

Chest radiographs show symmetrical hyperostosis of the sternum and middle thirds of the clavicles, with synostosis of the sternoclavicular joints. The upper ribs are variably involved, with early ossification of the costochondral

junctions. The disease appears to begin with an ossifying periosteitis. Biopsy of affected bones shows hyperostotic sclerosis of the spongiosa.

The aetiology is unknown, although there appears to be an association with ankylosing spondylitis and with vulgar or pustular psoriasis [108,110]. The disease is rare in the West, where it appears to be linked with HLA-B27, and is commoner in Japan where no such linkage occurs [110].

#### **Treatment**

No definitive treatment exists but symptomatic relief may be obtained with non-steroidal anti-inflammatory agents or with corticosteroids.

### **Tietze's syndrome or costochondritis**

This condition of obscure origin results in pain, swelling and tenderness of one or more of the upper six costal cartilage, although the sternoclavicular joint was thought to be involved in one of Tietze's original four cases [111]. It has been suggested that the condition is the mechanical consequence of differences in leg length [112]. Alternatively, on the basis of an 'epidemic' of six cases occurring within 6 weeks in Zambia, a viral aetiology has been proposed [113].

#### **Clinical features**

It may occur at any age although it is commoner in young adults. There is no sex predisposition. The most common presentation is with painful swelling of one or more of the upper six costal cartilages, most commonly the second. The pain is localized and may be described as aching, gripping, sharp or dull. The intensity varies from mild to severe and may be exacerbated by coughing or deep breathing [114,115]. The onset may be sudden or gradual and the condition may persist for weeks, months or, rarely, years [116]. Biopsy shows normal cartilage [117]. The blood picture, including ESR, is normal and there are no radiological changes.

#### **Treatment**

The majority of cases respond to reassurance and the passage of time with or without the administration of a minor analgesic. Exceptionally, local injection of hydrocortisone may be required for relief of symptoms [118].

### **Relapsing polychondritis**

This serious condition results in painful inflammation,

most commonly of the ear, nose and eyes, in association with systemic upset including fever, elevated ESR, anaemia and hyperglobulinaemia [119,120]. It is a disease of the middle decades with an equal sex distribution and is thought to be autoimmune in aetiology; antibodies to types IX and XI collagen and associations with systemic lupus and HLA-DR4 have been demonstrated [121–123]. Costochondral junction involvement is seen in about 50% of cases and laryngotracheal involvement in 70%. The disease may be rapidly fulminant, with death from pneumonia refractory to antibiotics or tracheal narrowing due to oedema, scarring and collapse of tracheal rings. Of the 49 cases reported in one series, the average lifespan of 11 who succumbed was 7 years, with a range from 10 months to 24 years [124]. The usual treatment is with systemic corticosteroids in a high initial dose (30–60mg) followed by a maintenance dose (5–10mg) [124]. Corticosteroids appear to suppress the fatal tracheo-bronchial complications of the disease. The use of stents may be necessary when tracheal or bronchial collapse is a problem [125].

## Rib defects

### Rib notching

Erosion of the inferior border of ribs or rib notching is most commonly seen in patients with coarctation of the aorta, when it is due to the enlarged intercostal arteries acting as collateral vessels (Fig. 45.5). It is present in 75% of adult patients but, since it is acquired, is less common in children although it has been seen in an infant [126,127]. The first two and last three ribs are never involved [126]. All other causes of this radiographic abnormality are rare, including subclavian artery obstruction after the Blalock–Taussig operation, ‘pulseless disease’, pulmonary arteriovenous fistula and intercostal neuroma. An idiopathic group is also recognized [126].

## Superior marginal rib defects

Loss of superior marginal cortical bone in the third to sixth ribs has been reported in patients with poliomyelitis and in patients with restrictive lung disease due to connective tissue disorders, such as rheumatoid arthritis, systemic lupus erythematosus and scleroderma [128–130]. The aetiology is unknown.

## Tumours of the chest wall

Tumours of the chest wall may originate in soft tissues or the bony thorax and the most common primary tumours found in these sites are shown in Table 45.2. Metastatic tumours of the chest wall are much more common than primary tumours.

### Soft tissue tumours

#### Benign tumours

Lipoma is the most common benign soft tissue tumour of the chest wall. It is characteristically spongy, transilluminates well and is readily identified by CT. Rarely it may extend into the pleural cavity giving rise to an hourglass-shaped mass that indents the lung [131].

Chest wall haemangiomas are slow-growing tumours that arise in striated muscle. As they enlarge they may produce radiographic evidence of rib hypertrophy and notching. Phleboliths are uncommon but pathognomonic. Eventually a pulsatile mass that may have an audible bruit may form and this may be mistaken for a metastasis from thyroid or renal carcinoma.

Cystic hygroma or cavernous lymphangioma is an uncommon thin-walled multilocular tumour, usually found in the region of the neck in small children, that may extend into the mediastinum and chest wall rendering

**Table 45.2** Benign and malignant tumours of the thoracic soft tissues and the bony thoracic cage.

	Benign	Malignant

**Fig. 45.5** Notching of the lower borders of upper thoracic ribs in a patient with aortic coarctation.

removal difficult. The author has seen haemorrhage into one such tumour cause acute tracheal obstruction (Fig. 45.6).

Multiple neurofibromas, varying in size from a pea to a ping-pong ball, may be found in the intercostal spaces of the chest wall (Fig. 45.7). They are associated with neurofibromas elsewhere in the body and with the characteristic *café-au-lait* spots. Rarely malignant change may occur, with sudden acceleration in the rate of growth of a nodule.

The fibrous benign desmoid tumour, which usually arises from the fascia of the anterior abdominal wall, has also been described arising in the intercostal space [132–134].

### **Malignant tumours**

Fibrosarcoma is the most common malignant soft tissue tumour of the chest wall and usually presents in young adults as a tumour in the region of the shoulder [133]. Haematogenous dissemination does happen but cure is possible if wide surgical excision is performed before this occurs.

Liposarcoma arises *de novo* and not from a pre-existing lipoma. It rarely metastasizes, although 50% recur after surgical resection.

Chest wall sarcomas including leiomyosarcoma have been reported in children and have proved amenable to surgical resection [135,136]. Malignant synovioma of the chest wall has also been reported [137]. A malignant chest wall tumour with features of adenocarcinoma and squamous carcinoma has been described 2 years after iodized talc pleurodesis [138]. Neuroectodermal tumours (Askin tumours) may occur in the chest wall. They are most frequent in children and may present as a large mass or with lung metastases [139].

### **Tumours of the bony thoracic cage**

Tumours of the bony thoracic cage are most commonly found in the ribs and least commonly in the sternum, with intermediate frequencies in scapula, thoracic vertebrae and clavicle. The most common tumours are metastases from other primary tumours, most often breast, bronchial and prostatic carcinoma. Prostatic and breast metastases in particular may be osteosclerotic (Fig. 45.8). Of primary

**Fig. 45.6** Barium swallow in a patient who presented with stridor showing tracheal displacement to left. At surgery the lesion proved to be a cystic hygroma into which an acute bleed had occurred.

tumours of the thoracic cage, approximately 50% are benign [140–144]. Secondary tumours tend to have a short duration of symptoms, averaging 3 months in one series, whereas the mean duration of symptoms averaged 4.1 years for primary benign and 1.7 years for primary malignant tumours in the same series [141]. Patients with benign tumours are half as old on average as those with malignant tumours and about 30% of all thoracic cage tumours are discovered on routine chest radiography [141].

Patients may be asymptomatic, although the most common presentation is with local pain, which may vary from a dull ache to pain of great severity, and a mass on the chest wall. The pain of benign lesions tends not to change, whereas that of malignant lesions tends to progress and may be more readily affected by movement and coughing [140]. Where local structures are infiltrated or compressed,

pleuritic pain and referred pain, for example from intercostal nerves, may occur. It is generally agreed that it is unwise to assume that a tumour of the thoracic cage is benign, and all tumours should be treated with wide excision so that a pathological diagnosis can be obtained on the entire surgical specimen.

#### *Benign tumours*

Osteochondroma or exostosis is the most common benign tumour, often presenting as a mass arising from the scapula or a rib, most frequently near the costochondral junction, in patients in the second decade. Growth begins in childhood and is believed to stop when adult stature is achieved. There is often a bony base to the tumour with a cartilaginous cap over which a bursa may be present. These tumours may cause local pain and

**Fig. 45.7** Three neurofibromas on left lateral chest wall in patient with multiple neurofibromatosis.

should be excised since the diagnosis is never certain and chondrosarcomatous transformation of the cartilage can occur.

Chondromas appear radiologically as well-demarcated expansions of a rib near a costochondral junction. A well-defined lucent area in the rib may contain flakes of calcium. Tumours of mature cartilage, they may give rise to chondrosarcomas and the treatment of choice is wide surgical excision.

Simple (or unicameral) bone cysts are found in the anterior portion of ribs, in the clavicle or sometimes in the head of the humerus. They produce a radiolucent defect on chest radiographs that may expand and thin the cortex resulting in a pathological fracture.

Osteoid osteoma is uncommon in the thoracic skeleton but may be confused with osteomyelitis or malignancy since it causes severe progressive pain that is worse at night. The radiographic picture of a round or oval lucent

area about 1 cm in diameter surrounded by sclerotic bone often assists diagnosis.

Fibrous dysplasia is the most commonly encountered rib abnormality in young adults aged 20–30 years [145, 146]. The condition is one in which primitive fibrous tissue proliferates in the medullary cavity and erodes the cortex from within, often producing expansion or distortion of the bone. The lesion is usually single and located in the posterior aspect of the ribs, although multiple lesions are found in Albright's syndrome where *café-au-lait* spots, precocious puberty or hyperthyroidism may be found [145]. Radiologically, the cortex may be thinned by a transradiant swelling that may be traversed by irregular bony trabeculae [140]. Clinically, pain is unusual but pathological fractures do occur. Excision is the treatment of choice [147].

Osteoclastoma is a rare tumour in the thorax, where it may be found in the head or tubercle of a rib; 10% are malignant and treatment is by excision.

**Fig. 45.8** Chest film of thoracic and upper lumbar spine showing radiodense osteosclerotic metastases from prostatic carcinoma.

### ***Malignant tumours***

Chondrosarcoma is the most common primary malignant tumour of the bony thoracic skeleton and presents usually with chest pain and swelling [140,141,148]. It has been described after radiation therapy, in Paget's disease and on one occasion following repetitive trauma from the arm of a wheelchair [149]. Most common in the upper anterior ribs, it is seen radiologically as a mass arising from the periosteum in such a way that the underlying bone shows minimal destruction (Fig. 45.9). Flakes of calcium may be seen in the tumour. It is locally invasive and may also spread via the bloodstream to the lungs in the first

instance. Treatment is by wide surgical excision and chemotherapy.

Ewing's tumour, an aggressively malignant tumour, is most common in those under 30 years of age and usually involves the ribs and less commonly the scapula or sternum [140,150]. Systemic features of fever, weight loss and malaise may occur with progressive local changes of pain, swelling and tenderness [150]. Radiographs may show progressive rib destruction with little reactive change and a soft tissue mass develops in most cases (Fig. 45.10). Multiple areas of periosteal new bone formation may produce an onion-peel appearance. The tumour metastasizes to lungs and other bones in most patients.

Treatment involves chemotherapy usually with combined radiotherapy and surgery; survival rates at 4 years of 56% have been reported after combined treatment, with no later recurrences [151].

Fibrosarcoma and osteogenic sarcoma behave like chondrosarcoma both clinically and radiologically [140].

Myeloma may present as a solitary lesion or as multiple lesions most commonly of the ribs [152,153]. The most common presenting feature is rib pain, often due to pathological fractures. Lytic lesions are seen on chest radiographs. Treatment consists of radiotherapy for local lesions and chemotherapy for multiple lesions.

## Infections of the chest wall

### Osteomyelitis

Osteomyelitis of ribs is relatively uncommon and is more frequent in children than adults. It often occurs after trauma and affects one of the upper three ribs, most commonly the first. The suppuration may strip the periosteum from the rib, forming a subperiosteal extrapleural abscess that may be large. Radiologically, the rib appearance may not change for 10–12 days. Initially, there is non-specific local destruction and osteolysis with reactionary sclerosis as the lesion becomes established [153].

Local osteomyelitis of a rib may be secondary to the drainage of an empyema, with infection spreading from the drainage site into the bone. Sequestra may be formed and discharge into the empyema, which persists until they are removed [154]. The most common offending microorganism is *Staphylococcus aureus*, management with appropriate antibiotics leading to resolution in most cases.

Osteomyelitis of the sternum is very uncommon [155,156]. It presents with fever and a tender swelling with radiographic evidence of bony erosion and sclerosis. *Staph. aureus* and *Pseudomonas aeruginosa* have been reported as causative organisms. Surgical drainage and curettage may be required in addition to antibiotic therapy [156].

### Septic arthritis

Sternoclavicular joint infection is an unusual cause of chest pain [157]. The joint is usually swollen and tender, with fever and systemic evidence of infection. The condition is commoner in heroin users in whom infection with both *Ps. aeruginosa* and *Staph. aureus* has been reported [158]. Treatment is with antibiotics and aspiration as required.

### Tuberculosis of the thoracic cage

Costal tuberculosis is rare but may give rise to local pain,

**Fig. 45.9** (a) Left lateral chest wall mass that on biopsy proved to be chondrosarcoma. CT shows (b) small metastatic deposits within the lungs and (c) soft tissue expansion round enlarged rib, containing dense areas of new cartilage. (Courtesy of Dr J.R. Walsh.)

**Fig. 45.10** Posterior mediastinal tumour. Destruction of the eighth rib provided the clue that this was a primary Ewing's sarcoma.

swelling and sinus formation. Radiologically there is an initial small area of bone destruction that may progress to periosteal elevation and soft tissue swelling. There is usually no evidence of pulmonary tuberculosis. Similar disease may arise in sternoclavicular or acromioclavicular joints.

Multiple lesions of the costovertebral portion of the ribs may accompany Pott's disease of the spine with paravertebral abscess formation.

#### **Cold abscess of the chest wall**

Cold abscess of the chest wall, which originates in tuberculosis of the intercostal lymph glands, can be divided into two main groups: the first lies at the angle of the ribs, from which the pus may track either backwards with the posterior primary division of the intercostal nerve, presenting near the erector spinae muscles, or forwards with the anterior division to present in the lateral chest wall; the second may arise from nodes in the region of the internal mammary artery and present near the costal cartilages. Cold abscess usually presents as a painless fluctuant swelling that may be mistaken for a lipoma. Diagnosis is made by aspiration of pus or during surgical exploration. It responds well to conventional antituberculous chemotherapy.

#### **Syphilitic gumma of chest wall**

This is now very rare and is described as arising in the

anterior mediastinum and giving rise to a hard, fixed lump in the intercostal space that may later soften and form a punched-out ulcer. Radiologically, the lesion may resemble a tumour of the anterior mediastinum. The true nature may be suspected if a punched-out ulcer has developed or as a result of positive serology.

#### **Actinomycosis**

Actinomycosis may spread from the lungs into the chest wall and give rise to destructive lesions with irregularity of the rib margins caused by periosteitis. It is described in Chapter 21.

#### **Echinococcosis**

Costal echinococcosis is very rare and usually presents as a multiloculated osteolytic lesion in rib [159]. The lesions are usually posterior and may expand to transgress the bony cortex. In the costovertebral region soft tissue masses may form and neurological presentations are common in this situation. The condition is described in Chapter 22.

#### **Fungal infections**

Blastomycosis, coccidioidomycosis and cryptococcosis can cause osteolytic lesions of ribs similar to those described above for tuberculosis. These organisms are discussed in Chapter 21.

### Thoracoplasty

This operation, in which a varying number of ribs was removed from one or both sides of the upper thoracic cage (Fig. 45.11), was widely practised from the 1930s until the mid-1950s as a treatment for tuberculosis [160]. In many cases it appears to have arrested previously progressive cavitating disease, one study carried out during the 1980s having shown survival of 93% at 10 years and 79% at 20 years [161]. However, the combination of the effects of the tuberculosis, the loss of the chest wall and, often, smoking has in many cases resulted ultimately in the development of respiratory failure.

### Neuromuscular conditions affecting respiration

It is uncommon but not unknown for patients with neurological disease to present primarily to the chest physician. However, respiratory problems in the course of neurological disease occur frequently, and the advice of someone interested in respiratory management is often sought. These conditions may be separated into those causing acute ventilatory problems and those causing chronic failure (Table 45.3).

### Acute respiratory failure

Acute problems occur most commonly as a consequence of overdose of drugs with a central nervous depressant effect, such as barbiturates and opiates, producing hypoventilation and carbon dioxide retention [162]. Management of these episodes includes a requirement for ventilatory support and, if necessary, cardiac support. Alcohol may not only cause central respiratory depression but has also been described as causing an acute rhabdomyolysis after a prolonged drinking bout [163]. A unique drug-induced cause of respiratory failure is the myasthenia syndrome that occurs as a rare side-effect of treatment with D-penicillamine, which usually resolves when the drug is discontinued [164]. Organophosphate and carbamate poisoning as a result of the widespread and careless use of insecticides is a not uncommon cause of acute respiratory failure in underdeveloped countries [165]. Similar problems occur as a result of neurological disease in acute ascending polyneuritis (Guillain-Barré syndrome), poliomyelitis, status epilepticus, tetanus and myasthenia gravis; as a result of accidents, following high spinal cord trauma and air embolism in diving; and as a consequence of lesions causing acute rises in intracranial pressure. Hypothyroidism may cause respiratory failure by a combination of central respiratory depression, upper airway

**Fig. 45.11** Right-sided eight-rib thoracoplasty carried out for cavitating tuberculosis in the late 1940s. Calcified lesions of healed tuberculosis are visible in both lungs.

**Table 45.3** Neuromuscular causes of ventilatory failure.

	Acute	Chronic
Neurological disease	Acute polyneuritis Poliomyelitis Myasthenia gravis Cerebral haemorrhage Cervical cord injury High intracranial pressure Epilepsy Critical illness neuropathy Tetanus Air embolism Hypothyroidism Bilateral phrenic palsy	Motoneurone disease Poliomyelitis Cervical cord injury Idiopathic Ondine's curse Brainstem tumours Myasthenia gravis Eaton–Lambert syndrome Multiple sclerosis Bilateral phrenic palsy Hypothyroidism Parkinson's disease
Muscular disease	Acute polymyositis Dermatomyositis Steroid myopathy Hypokalaemia	Muscular dystrophies Acid maltase deficiency Dystrophia myotonica Rigid spine syndromes Nemaline myopathy
Drugs' poisons	Opiates Barbiturates Hypnotics Anaesthetics Muscle relaxants D-Penicillamine Alcohol Botulinus toxin Organophosphates Carbamates	

obstruction and perhaps respiratory myopathy [166,167]. Acute respiratory muscle paralysis may occur in hypokalaemia [168], most commonly of the familial type but whatever the cause, and as a result of muscular or peripheral nerve dysfunction occurring in patients acutely ill on respirators [169–171], where it may cause problems in weaning from the machine. A steroid myopathy has also been described as causing similar problems [172], and this is something to be considered especially in severe asthma attacks when a patient has required ventilation and is proving difficult to wean. Primary muscle disorders may cause acute respiratory failure, particularly those having an inflammatory basis such as polymyositis and dermatomyositis [173].

### Chronic respiratory failure

Chronic ventilatory failure may be due to lesions involving the respiratory centre in the floor of the fourth ventricle, the nerves of the respiratory reflex arc or the muscles of respiration. The sleep apnoea syndromes are discussed in Chapter 47, although it should be noted that sleep hypoventilation is a usual accompaniment of all neuromuscular syndromes affecting respiration. The most common neurological causes of chronic ventilatory failure are motoneurone disease [174], poliomyelitis [175], multiple sclerosis [176] and spinal cord transection.

Chronic hypoventilation may also occur in myasthenia gravis [177], Eaton–Lambert syndrome [178] associated with bronchial carcinoma, hypothyroidism [179] and Parkinson's disease [180,181]. The drug L-dopa, used in the treatment of Parkinson's disease, may also cause respiratory muscle and respiratory centre dysfunction leading to ventilatory insufficiency [180]. Ondine's curse, a condition in which there is failure of brainstem autonomic control leading to suppression of respiratory drive when the subject is asleep, occurs as a congenital defect or may be a consequence of stroke or other pathological processes in the respiratory centre [182]. Bilateral phrenic nerve palsy has been discussed above. Muscle diseases causing chronic respiratory failure [173] include muscular dystrophies, of which the limb girdle and Duchenne types are the most common, adult acid maltase deficiency [183], dystrophia myotonica, rigid spine disorders including Emery–Dreifuss syndrome, and the autosomal dominant nemaline myopathy that sometimes presents in adult life.

### Assessment of respiratory function

In neuromuscular ventilatory failure the patient may remain asymptomatic from a respiratory point of view because of the inactivity imposed by the primary disease [184]. As the condition progresses, the patient may be seen

to be breathing rapidly and shallowly, except when the cause is drug overdose or brainstem disease, when the rate may be much reduced. Daytime somnolence is often present. The cause is usually obvious from the symptoms and signs of the primary disease, and treatment should be directed at its alleviation where possible. Thus it is important not to miss the less obvious causes such as hypokalaemia in, say, periodic paralysis, myxoedema or poisoning with organophosphorus insecticides. Physical signs may include the paradoxical chest wall and abdominal movements described in the section on diaphragmatic paralysis, poor cough, and difficulty with speech and swallowing. Vital capacity may be reduced but is often normal until the condition is quite advanced; nevertheless, at an earlier stage it should be possible to demonstrate reduced MVV and maximal inspiratory pressures using an oesophageal balloon. Sleep studies are essential, as the condition is usually worse during this time and in a number of conditions both central and upper airway dysfunction combine to cause the respiratory failure. In conditions with a fluctuating or progressive course, serial measurement of vital capacity is a useful means of monitoring progress and assessing the need for ventilatory assistance.

## Management

Wherever possible treatment should be directed at the primary cause. General management includes assistance with coughing and treatment of any respiratory infections, although the important decision relates to the need for ventilatory assistance. This clearly depends on the primary condition and its other effects on the patient, and there is little problem in deciding to use this in acute venti-

latory failure. Increasingly, however, patients with chronic neuromuscular conditions who would not have been considered suitable for long-term ventilation a decade ago are now benefiting from advances in management, which may provide fewer hospitalizations and respiratory infections and a better quality of life. Most such patients should be considered for such treatment [185]. In this chronic situation, there is time for detailed discussion of the implications of long-term support with patients and relatives, and for assessment of their suitability for domiciliary ventilation [186]. It is usually desirable to start with non-invasive measures and to delay tracheostomy until it becomes essential. Administration of low-flow oxygen to such patients without assisted ventilation is likely to give rise to carbon dioxide retention and is therefore undesirable [187]. A simple rocking bed may be suitable in some cases, where diaphragmatic weakness predominates or in relieving symptoms in terminal care [173]. The methods of ventilatory support available are described in Chapter 58. After full assessment, including polysomnography, the patient is often helped by nasal intermittent positive-pressure ventilation during the night. As the condition progresses it is often necessary to convert to intermittent positive-pressure ventilation via a permanent tracheostomy. In some cases a cuirass respirator is found to be more suitable (see Chapter 58).

All patients with chronic ventilatory failure reach a stage at which their quality of life seems not to justify initiation or continuation of ventilation, a matter that should be as fully discussed as practicable with patient and relatives. When the decision is made, some expertise in the use of drugs and ventilators is required to ensure that the gradual withdrawal of support does not cause undue distress.

# ABNORMALITIES AND DISEASES OF THE DIAPHRAGM

ANTHONY SEATON

The diaphragm is the most important muscle of respiration. It is rarely affected by intrinsic disease but because of its complex embryological development is subject to a number of congenital anomalies. Primary disorders of the diaphragm may present with symptoms suggestive of intrathoracic disease. Conversely, radiographic abnormalities of the diaphragm may indicate disease in the chest or abdomen.

## Embryology

The arched musculotendinous division between the thorax and the abdomen has its origin in vertebral, costal and spinal attachments from which muscular fibres curve upwards and inwards from the periphery to be inserted into the fibrous sheet called the central tendon [1]. The diaphragm derives developmentally from four sources [2].

1 The *septum transversum* is first seen at the third week of development as a mass of mesoderm situated cranial to the pericardial cavity. This structure contributes to the more ventral portions, i.e. the sternal and costal parts.

2 The second source is derived from paired dorsolateral portions, the *pleuroperitoneal membranes*, which fuse with the dorsal mesentery of the oesophagus and the dorsal portion of the septum transversum to complete the partition between the thoracic and abdominal cavities and form the primitive diaphragm at about the seventh week of development.

3 The median portion of the diaphragm is derived from an irregular medial dorsal portion of primary oesophageal mesentery that fuses with the septum transversum and pleuroperitoneal membranes. The curves of the diaphragm develop from the growth of muscle fibres into the dorsal mesentery of the oesophagus.

4 During weeks 9–12 the fourth source is contributed by marginal ingrowths of the body wall. These contributions from the thoracic myotomes also contain nerve fibres of the lower six or seven intercostal nerves that distribute sensory fibres to the peripheral parts of the diaphragm.

During the development of the diaphragm, striking positional changes of its components are seen. At the third or fourth week the septum transversum lies opposite the upper cranial somites. During the fifth week nerve fibres from the third, fourth and fifth cervical segments of the spinal cord grow into the septum transversum via the pleuropericardial membranes and together constitute the phrenic nerves, which in adult life lie within the fibrous pericardium.

A more rapid growth of the dorsal embryo results in an apparent migration of the diaphragm, which by the sixth week is at the level of the thoracic somites. The phrenic nerves are also lengthened. By the beginning of the eighth week, the diaphragm is attached to the dorsal body wall at the level of the first lumbar vertebra, giving the diaphragm the domed contour characteristic of its adult form. In the adult a threefold variation in diaphragm muscle mass has been recorded, being related to an individual's overall muscularity [3].

## Radiological appearances

The right hemidiaphragm is usually higher than the left, the average level of the right dome being at the anterior end of the sixth rib [4]. The left hemidiaphragm lies half an interspace lower than the right but appreciable unilateral elevation is not uncommon [5]. In one study a raised diaphragm was seen on the left in 9% and on the right in 2% of 500 normal chest films [6]. In half the individuals with a raised diaphragm on the left the two domes were at the same level, while in the other half the left was actually higher than the right.

The normally higher position of the right hemidiaphragm is usually and illogically attributed to the bulk of the underlying liver, but the truth is that the left hemidiaphragm is depressed by the heart. In partial situs inversus with liver and heart on the same side, the diaphragm is lower on that side [7]. Inversion of the diaphragm may occur on both the right and left sides, most commonly as the result of a massive pleural effusion or a tension pneu-

mothorax. Difficult to demonstrate on a plain chest radiograph, it is readily detected by ultrasound examination [8].

Unequal excursion of the two hemidiaphragms is normal [5]. In one series the hemidiaphragms moved asynchronously in 77%, although the difference in excursion was usually less than 1 cm [9]. The excursion in this group of normal subjects ranged from 3 to 6 cm in 75%, with 23% showing excursion of less than 3 cm and 2% more than 6 cm. Unilateral paradox on sniffing has been seen in up to 6% of normal subjects and is more common on the right [10].

## Function

In normal quiet breathing the diaphragm is responsible for 75% of inspiration and the intercostal muscles for 25%. Contraction of the diaphragm leads to its descent, with a resultant rise in intra-abdominal pressure and movement of the abdominal wall outwards [11,12]. A secondary effect of diaphragmatic contraction is to elevate and push the lower ribs outwards [13]. This secondary action is a function of the costal parts of the diaphragm, for when the costal parts only are stimulated the diameter of the lower rib cage increases [14,15]. During severe hyperinflation, as seen in chronic bronchitis and emphysema, contraction of the diaphragm produces paradoxical inward movement of the lower rib cage or Hoover's sign [15].

Diaphragmatic function may be assessed clinically by checking for appropriate thoracic and abdominal wall movements during inspiration and by performing tidal percussion, although one study found poor correlation between chest radiographic and clinical measures of diaphragmatic movement and wide interobserver variation [16]. Fluoroscopy allows diaphragmatic movement to be examined and is the conventional method of screening for diaphragmatic paralysis in patients with bronchogenic carcinoma. With paralysis of the diaphragm, the affected side descends poorly on inspiration and should move paradoxically upwards during a sniff. However, contraction of abdominal muscles may confound the findings, allowing apparently normal movement of a paralysed diaphragm [13].

Phrenic nerve stimulation, with recording of the diaphragmatic action potential using either oesophageal electrodes or surface electrodes over the lateral chest wall, allows the measurement of phrenic nerve conduction time. Unfortunately, the amplitude of the action potential is not an absolute index of diaphragmatic function. The most sensitive index of function is the measurement of transdiaphragmatic pressure ( $P_{di}$ ) during a quiet and a maximal inspiration. Pressures are recorded from balloons in the oesophagus and the stomach; in normal subjects  $P_{di}$  increases by 5–8 cmH<sub>2</sub>O in a quiet inspiration and by more than 25 cmH<sub>2</sub>O during a maximal inspiration. In bilateral

diaphragmatic paralysis no change in pressure occurs [13]. Even this index of diaphragmatic function has been criticized because of the wide range of normal values for maximum  $P_{di}$  (18–137 cmH<sub>2</sub>O) occasioned by interindividual variation in utilization of accessory muscles [17]. It has been suggested that measurement of  $P_{di}$  during a maximum sniff is of more value in detecting diaphragmatic weakness or paralysis (normal value 112–204 cmH<sub>2</sub>O) [18].

## Disorders of function

### Diaphragmatic fatigue

The diaphragm shares with the myocardium continuing regular activity of varying degree throughout life. Not surprisingly the muscle fibres comprising the diaphragm show a predominance of fibre types relatively resistant to fatigue; 50% are type I or slow-twitch fibres, with a high oxidative and low glycolytic capacity, and 20% type IIA or fast-twitch fibres, with both high oxidative and glycolytic capacities. The remaining 30% are type IIB or fast-twitch fibres, with low oxidative capacity and high glycolytic activity, and are relatively susceptible to fatigue [19–22].

At its customary resting length the human diaphragm only becomes fatigued when the force of contraction during inspiration exceeds 40% of the force that it can develop in a maximal static effort. During tidal breathing it operates at only about 10% of maximal [23]. The more the respiratory force exceeds 40%, the sooner the onset of fatigue [19]. Development of fatigue can be demonstrated by stimulating the phrenic nerve and constructing  $P_{di}$ -phrenic nerve stimulation frequency curves [24,25]. Fatigue produced in normal humans, for example by breathing through an inspiratory resistance for as long as possible, results in a reduction of force developed at all frequencies with a preferential reduction at low frequencies [26]. This 'low-frequency fatigue' is believed to represent a failure of excitation-contraction coupling in the muscle [13]. It has been shown to occur in normal individuals as a consequence of exhausting exercise and the exertions of the later stages of labour [27,28].

An alternative technique for detecting diaphragmatic fatigue is to record the power spectrum of the diaphragmatic electromyogram (EMG) using oesophageal or surface electrodes [13,26]. A decrease in the ratio of high-frequency to low-frequency power in the EMG indicates fatigue. Using this technique, fatigue has been detected in the normal newborn diaphragm when rib cage distortion is present [29]. The technique has also been used to detect fatigue early in neonates being weaned from a ventilator before the onset of clinical signs or carbon dioxide retention [30]. The predisposition of the neonate to diaphragmatic fatigue is presumably a reflection of the relative

absence of type I muscle fibres in the infant diaphragm; premature infants have only 10% type I fibres and the full-term newborn only 25%. The adult proportion of 50% type I fibres is only achieved at 8 months [31]. In adults with chronic obstructive pulmonary disease, the force reserve of the diaphragm has been shown to be greatly reduced so that slight modifications of the pattern of breathing can bring the diaphragm above the fatigue threshold [32].

### *Clinical features*

Two physical signs of diaphragmatic dysfunction are recognized. Prominent rib cage movement in the supine position indicates recruitment of other respiratory muscles and is a feature of any disease or condition that leads to increase in the work of breathing. More importantly, indrawing of the anterior abdominal wall during inspiration (when not due to abdominal muscle contraction) is a significant indication of diaphragmatic fatigue or paralysis [33,34]. In patients being unsuccessfully weaned from ventilators, the sequence of events that culminates in respiratory acidosis has been described [20]. Initial EMG evidence of fatigue either precedes or accompanies an increase in respiratory rate. This is followed by alternation between abdominal and rib cage breathing (respiratory alternans) and then by a paradoxical inward motion of the abdomen during inspiration (abdominal paradox). Finally, minute ventilation and respiratory rate fall with a resultant increase in  $P_{aCO_2}$ .

### *Management*

The immediate management of diaphragmatic fatigue, which is probably present in all cases of life-threatening respiratory failure, involves ventilatory support with positive-pressure ventilation to allow recovery of the fatigued muscle while the precipitating factor is treated. In the longer term, in subjects predisposed to fatigue by virtue of associated disease such as chronic obstructive airways disease, quadriplegia and cystic fibrosis, ventilatory muscle training, which involves breathing against an inspiratory resistance for 30 min daily, increases both the strength and endurance of the diaphragm as well as protecting against fatigue [35–39]. Pharmacological intervention also seems possible since both aminophylline [40] and caffeine [41] have been shown to increase the contractility of the diaphragm and to increase the pressure the diaphragm develops at a constant frequency of phrenic nerve stimulation after fatigue [40].

Finally, in selected subjects, particularly quadriplegics with ventilatory failure, implanted receivers with electrodes stimulating the phrenic nerves have been used successfully in treatment. This procedure, which is restricted to a few specialist centres, involves placing a radio

receiver subcutaneously with electrodes leading to the phrenic nerve usually in the neck. An external battery-powered transmitter controls the receiver and can be used to modify respiratory rate and the depth of inspiration. Each phrenic nerve is paced alternately for 8 h in order to avoid diaphragmatic fatigue [42].

## **Diaphragmatic paralysis**

### **Unilateral paralysis**

#### *Aetiology*

The phrenic nerve is derived from the C3–C5 nerve roots and may be affected by compression, inflammation or injury anywhere in its course from cervical spine to diaphragm. The most common cause of unilateral diaphragmatic paralysis is involvement of the phrenic nerve by bronchogenic carcinoma. Such involvement by tumour above the pulmonary hilum excludes surgical treatment, although when the lesion is below the hilum resection of the tumour, nerve and pericardium may be attempted. The causes of unilateral diaphragmatic paralysis are shown in Table 46.1 [43].

Sometimes phrenic paralysis occurs without satisfactory explanation. In the days of mass miniature radiography, it was not uncommon to recall patients in whom the film had shown an elevated hemidiaphragm and who were shown to have paralysis on screening. Such patients often gave a history of a transient febrile illness, often associated with chest or shoulder pain; no other cause was found and led to the problem being attributed to a 'viral infection'. The recent evidence that idiopathic facial nerve palsy is often caused by herpes simplex virus 1 [44] suggests that this may not have been wide of the mark. Indeed, cervical herpes zoster is a known cause of diaphragmatic paralysis [45]. This appears to be analogous to the so-called neuralgic amyotrophy that affects the deltoid muscle and is attributed to inflammation of the C5–C7 nerve roots; diaphragmatic paralysis, both unilateral and bilateral, has been found in this condition [46].

The 'paralysis' seen in association with supraphrenic or subphrenic infection may be more apparent than real. In such subjects the diaphragm is often elevated and immobile but recovery occurs as the infection clears. The same is true of the elevation of the diaphragm associated with pulmonary embolism.

#### *Clinical features*

Paralysis of a hemidiaphragm alone does not usually give rise to symptoms, and where symptoms are present they usually reflect the causative disease. Altered diaphragmatic movement may be detected by careful

percussion, although this sign requires practice to elicit and is associated with substantial interobserver variation [16].

### Radiology

The affected diaphragm may or may not be elevated and shows paradoxical movement on respiration. This is confirmed by fluoroscopy and may be accentuated by asking the patient to sniff, when the affected hemidiaphragm rises while the unaffected hemidiaphragm moves downwards. As discussed above, the diagnosis may not always be clear-cut even on screening, and ultrasonography has proved a useful means of confirming the radiological suspicions [51].

### Functional effects

Unilateral paralysis of the diaphragm reduces vital capacity by 20–25% in the upright posture, with a further 10–20% reduction in the supine position [52–54].  $P_{aO_2}$  may fall in the supine position due to an increase in closing volume, and compression of basal lung segments on the affected side has been demonstrated bronchographically [52,53]. A 20% reduction in ventilation and perfusion to the lung on the affected side has also been shown [52,55].

### Management

In the large majority of cases, no treatment is necessary as the condition is symptomless. Occasionally, however, the development of unilateral paralysis in someone with severe pulmonary impairment precipitates ventilatory failure. This has been described particularly after lung or cardiac surgery [56–58]. In such circumstances recovery may take place with time, such as when the paralysis occurred as a consequence of phrenic stretching or hypothermia, and ventilatory support may be all that is necessary. If recovery does not occur, diaphragmatic plication has proved to be an effective method of improving lung mechanics and the patient's condition [59,60].

### Bilateral paralysis

#### Aetiology

Paralysis or weakness of both hemidiaphragms is uncommon and may be idiopathic in origin [61], follow viral infections [62] or blunt trauma to the chest [63], or occur in association with rare neuromuscular diseases as well as the more common quadriplegia following trauma [46,64–70] (Table 46.2). A similar condition may occur in systemic lupus erythematosus [71].

### Clinical features

Dyspnoea is a usual feature of bilateral diaphragmatic paralysis as is paradoxical inward movement of the abdominal wall during inspiration, both particularly marked when the subject is in the supine position [13]. Respiratory rate is usually increased with a reduction in tidal volume. Alveolar hypoventilation may occur during sleep [63,72] with resultant carbon dioxide retention leading to disturbed sleep, morning headaches and daytime fatigue with hypersomnolence [66]. There may be associated sleep apnoea [61].

### Radiology

Both diaphragms may be elevated on the chest film, move sluggishly or paradoxically with inspiration, and paradoxical movement should be (but is not always) seen during sniffing [65]. That fluoroscopy can be misleading is due to contraction of abdominal muscles during expiration, which pushes the diaphragm up passively and allows it to descend passively and apparently normally during inspiration [13].

### Functional changes

In complete bilateral diaphragmatic paralysis, *P<sub>di</sub>* does not change during tidal breathing or a maximum inspiration, while reduced changes in pressure are seen in patients with bilateral weakness [13,67,68,72]. Vital capacity is reduced in the upright position and further decreased in the supine position [63,73]. Similarly, *P<sub>aO<sub>2</sub></sub>* is reduced and falls further on lying down. Studies have shown that the ventilation–perfusion ratio is the same in both lungs in a normal subject occupying the lateral decubitus position, whereas it is substantially reduced in the dependent lung of patients with bilateral diaphragmatic paralysis, a phenomenon that must contribute to the postural hypoxia via shunting of blood [74]. Measurement of pressure–volume relationships in diaphragmatic paralysis has disclosed decreases in both maximal transpulmonary pressure and static compliance [75]. The reduced compliance, tentatively ascribed to microatelectasis, may explain the rapid respiratory rate in these patients.

### Management

Although spontaneous improvement in diaphragm function has been seen [68], permanent paralysis is the rule. Some patients have benefited from the use of a cuirass respirator at night to manage the associated respiratory failure [65], and it would seem reasonable to apply the principles of management, including the use of nasal continuous positive airway pressure, described in Chapter 58.

The use of diaphragmatic pacing has already been mentioned [42].

## Involuntary movements of the diaphragm

### Hiccup

Sudden inspiratory spasm of the diaphragm with associated closure of the glottis (hiccup, or singultus for the obscurantist) is a familiar and harmless symptom in the normal subject, usually caused by gastric distension. EMG recordings have demonstrated synchronous electrical discharge in both the diaphragm and external (inspiratory) intercostal muscles [76]. The usual cause is a reflex transmitted by vagal efferents, via vagal and respiratory nuclei in the medulla, and phrenic nerves to the diaphragm and by somatic nerves to other respiratory muscles. Occasionally the symptom becomes persistent and distressing to the patient, especially in uraemia and neurological disease [77]. The best-recognized causes of persistent hiccup are shown in Table 46.3 and reflect the reflex pathway. It has been suggested that some apparently idiopathic cases may be a vagal analogue of trigeminal neuralgia and hemifacial spasm, where the neural hyperactivity may be triggered by contact between nerve and blood vessel [78].

### Treatment

Treatment depends on the cause and severity. Everyone is familiar with the various empirical homely remedies recommended for transient hiccup that act via vagal stimula-

**Table 46.3** Causes of hiccup.

<i>Local causes, stimulating vagal afferents</i>
Gastric distension or inflammation

Multiple sclerosis
Viral encephalitis, including HIV
Meningitis

HIV, human immunodeficiency virus.

tion. More persistent episodes may respond to stimulation of the pharynx with a catheter introduced through the nose [79]. This intervention is believed to initiate afferent vagal impulses that inhibit the hiccup reflex. Prolonged or distressing hiccup requires investigation and removal of the cause. If this is not possible, it may respond to intravenous injection of 50mg chlorpromazine [80]. Other drugs used have included haloperidol, metoclopramide, baclofen, antiepileptics and antidepressants [77,81]. In exceptional cases, phrenic nerve block by local anaesthetic or phrenic nerve crush has been used but is not recommended since it impairs lung function and is usually only partially successful. In one rather dramatic instance, neurosurgical separation of the vagus from contact with the posterior inferior cerebellar artery appears to have relieved the condition [78].

### **Tonic spasm of the diaphragm**

Tonic spasm may complicate rabies, tetanus and strychnine poisoning and less commonly pregnancy toxæmia, encephalitis and epilepsy. It results in upper abdominal pain and dyspnoea, and may necessitate assisted ventilation.

### **Diaphragmatic tic or flutter**

Diaphragmatic tic or respiratory myoclonus was first diagnosed and described by van Leeuwenhoek, the inventor of the microscope, who himself suffered from the condition [82]. It can occur at any age and in most cases the aetiology is unknown, although encephalitis and assorted causes of phrenic nerve irritation have been implicated in some [83]. The diaphragm or one hemidiaphragm contracts irregularly, with an average frequency of 150/min (range 35–480); the EMG shows bursts of electrical activity during inspiration and expiration [84,85].

#### *Clinical features*

Episodes may be precipitated by emotion, eating, exercise or assorted respiratory manoeuvres, and may last only a few seconds or persist for months. Attacks are usually associated with upper abdominal or lower chest pain that may mimic angina. Respiratory distress may occur and stridor and apneustic respiration (a prolonged breath-hold in inspiration) have been reported [86,87]. Other symptoms include belching, hiccups and retching. In some subjects epigastric pulsations may be seen, and if the stomach is full a rhythmic splashing sound may be heard [88]. Fluoroscopy demonstrates the abnormal movement of the diaphragm, which may also distort an ECG tracing [85]. The diagnosis may be confirmed if necessary by diaphragmatic EMG [89].

#### *Treatment*

Treatment with phenytoin 400mg daily or carbamazepine has been successful in some cases [85,89], but others have required phrenic paralysis by crush or injection of local anaesthetic [86,88].

## **Infection**

### **Subphrenic abscess**

#### *Clinical features*

Subphrenic abscess may occur spontaneously due to perforation of a viscus, amoebic liver abscess or pancreatitis, or may follow abdominal surgery [90–94]. Such abscesses may occur on either or both sides. Features include local costal or subcostal pain and tenderness, unexplained fever, tachycardia and leucocytosis. If antibiotics have been taken, the course may be more chronic with vague pains, chronic ill-health, unexplained fever and anaemia [95]. Its importance for the chest physician lies in the associated changes that may be seen on a chest film or on fluoroscopy.

#### *Radiology*

The most common finding is an elevated hemidiaphragm on the affected side with diminished movement of the diaphragm, although it should be noted that a reduction in diaphragmatic activity is a normal finding after upper abdominal surgery [96]. Other frequent findings include blunting of the costophrenic angle, pleural effusion and pulmonary infiltrates or atelectasis. Air–fluid levels may be seen in the abscess cavity. Fixation of the diaphragm and displacement of intra-abdominal viscera may be seen. Radiologically, it may be difficult to differentiate between a subphrenic abscess and a subpulmonary collection of fluid. Multiplanar ultrasonography, especially on the right side, and CT are useful means of making the diagnosis [94,97–99]. Outlining of a hemidiaphragm by contrast medium during pulmonary angiography has been reported in subdiaphragmatic inflammation [100], although it is not recommended that such an investigation be routinely employed! Scanning techniques using gallium–technetium subtraction or following injection of gallium-labelled leucocytes have also proved useful in the localization of subphrenic abscesses [101,102].

#### *Treatment*

The management of subphrenic abscess is by surgical drainage and appropriate antibiotic therapy [103]. Percutaneous drainage under ultrasonic or fluoroscopic guid-

ance using wide-bore catheters has been used with some success by those with special expertise [104].

**Trichiniasis**

One of the few primary diseases of the diaphragm is trichiniasis. When ingested in undercooked pork, or much less commonly bear meat, the larvae of the nematode *Trichinella spiralis* may be freed in the intestines where mating of male and female produces new larvae that can penetrate the intestinal wall and enter the bloodstream. Their subsequent fate is variable: some settle in organs where they die out; others reside in the muscles, including the diaphragm, where they may remain alive for years, subsequently becoming encysted.

*Clinical features*

The phases of intestinal invasion and encystment are usually symptomless but may be accompanied by diarrhoea and vomiting. The main symptoms usually occur 1 or 2 weeks after ingestion. These include fever, oedema that may affect the face only or be more widespread, muscle aches, skin rashes, chest pain (usually attributed to involvement of the intercostal muscles and diaphragm), hiccup, cough and haemoptysis (due probably to parasites in the lung). Respiratory failure secondary to weakness of the diaphragm and intercostal muscles has been described [105,106].

*Investigations*

Eosinophilia is a fairly constant and early feature and the parasite may be recovered from the blood in the early stages. Other diagnostic procedures in a suspected case are muscle biopsy (after the third week) and skin and precipitin tests with *Trichinella* antigen. In long-standing cases the calcified larvae are visible in muscles on the chest radiograph.

*Treatment*

The condition is usually self-limiting and no treatment is required. In severe cases treatment with corticosteroids and tiabendazole (thiabendazole) 25 mg/kg daily may be required. Prevention is the most important aspect of management of trichiniasis and the disease can be eradicated by making it known that the longer pork is cooked, the safer it is.

**Tumours**

Primary tumours of the diaphragm are exceedingly rare, and secondary tumours usually only occur as a direct extension from lung, liver or pleura.

**Metastatic tumours**

Metastatic tumours of the diaphragm are more common than primary tumours. Few are blood-borne, the majority occurring by seeding across serous membranes, infiltration from lung through pleura or direct spread, for example from the stomach [107]. The most common extrapleural primary sources are breast, ovary and stomach, while local involvement by bronchogenic carcinoma and mesothelioma is also seen. Mesothelioma is a tumour that is increasing in frequency in the UK, and it commonly involves the diaphragmatic pleura (see Chapter 43).

**Benign tumours**

Benign primary tumours occur more frequently than malignant ones [108]. The most common is the lipoma, which presents radiologically as a smooth rounded mass with a lower border continuous with the diaphragm [109]. The mass, which may appear less dense than would be expected on the basis of its size, usually arises from the posterolateral portion of the hemidiaphragm, more commonly on the left.

Other benign tumours include fibroma, angiofibroma, neurofibroma, neurilemmomas and haemangiopericytomas [110–113]. Angiofibromas may be calcified [111]. Mesothelial cysts may arise in relation to the pleuroperitoneal canal [112].

**Malignant tumours**

Most malignant tumours are of mesenchymal origin and the range of histological types is shown in Table 46.4 [111–113]; fibrosarcoma is the most common.

*Clinical presentation*

Malignant diaphragmatic tumours may present with severe lower chest or hypochondrial pain that radiates

**Table 46.4** Some malignant tumours of the diaphragm.

Malignant synovioma

along intercostal nerves or to the shoulder [112,113]. The pain is usually exacerbated by respiration and may be associated with cough, dyspnoea or upper gastrointestinal symptoms. A haemorrhagic pleural effusion may be present. A bulging of the hypochondrium that moves with respiration may occur. A palpable mass is found in 10%. Hypertrophic pulmonary osteoarthropathy has been described in 10% of cases [112]. The tumour may metastasize or invade lung locally.

### Diagnosis

On radiography a mass is seen in the lower thorax that is difficult to separate from surrounding structures. On fluoroscopy the mass is seen to move with the diaphragm. Pneumoperitoneum and pneumothorax may be needed to confirm that the mass arises from the diaphragm. CT may be helpful in diagnosis and in particular may identify lipomas by their decreased radiodensity.

### Management

If possible, surgical excision is indicated, with local repair using fascia lata or prosthetic material [114].

## Disorders of structure

### Eventration of the diaphragm

Eventration of the diaphragm is a condition in which all or part of the diaphragm is largely composed of fibrous tissue with only a few or no interspersed muscle fibres [115,116]. It is usually congenital but may be acquired.

#### Complete eventration

Complete eventration almost invariably occurs on the left side and is characterized by elevation of the left hemidiaphragm (Fig. 46.1), which on screening is virtually immobile and which moves paradoxically on sniffing. The condition is usually asymptomatic in adults but occasionally upper gastrointestinal symptoms such as undue flatulence may occur and operation, with plication of the diaphragm, has occasionally been undertaken because of the severity of dyspeptic symptoms [117]. In many patients barium examination shows the stomach to be inverted beneath the hemidiaphragm.

In infants, diaphragmatic eventration may occur on either side and may give rise to severe respiratory symptoms such as cough, dyspnoea and wheeze. Recurrent bronchopneumonia with associated dyspnoea and cyanosis may be seen. Anorexia and vomiting are less common. On examination there may be bulging of the affected hemithorax and a scaphoid abdomen. Fluoroscopy may show a 'dicrotic-like' pattern of diaphragmatic movement, with the lax portion of diaphragm

**Fig. 46.1** Posteroanterior (a) and lateral (b) chest films showing complete eventration of the left hemidiaphragm.

moving initially in a paradoxical manner followed by normal contraction of the periphery. Treatment by diaphragmatic plication usually gives excellent clinical and radiographic results [118,119]. However, a proportion of these patients have other congenital anomalies, including neurological and bowel disorders, that may influence their clinical outcome [120].

### Partial eventration

Partial eventration of the diaphragm occurs virtually exclusively on the right side. It is detected as an antero-medial bulge of the diaphragm that moves paradoxically on respiration [121] (Fig. 46.2). There is usually a corresponding deformity of the liver or 'superior accessory lobe' that can be demonstrated by pneumoperitoneum, liver scan or ultrasound examination [122,123]. Ultrasound is particularly useful in differentiating eventration from diaphragmatic hernias and pleuropericardial cysts, both of which it may closely resemble. Liver inversion with a suprahepatic gallbladder has been reported in association with partial eventration [124].

### Duplication of the diaphragm

An accessory diaphragm is a rare abnormality usually found in the oblique fissure on the right where it separates

all or part of the lower lobe from the rest of the lung [125–127]. It may be fibrous or muscular and contains a defect through which the normal bronchovascular supply passes to the lower lobe. Radiologically, thickening of the oblique fissure with elevation of the right hemidiaphragm may be apparent. It may be associated with neonatal respiratory distress; where the accessory diaphragm is muscular, bronchiectasis of the right lower lobe may result.

### Diaphragmatic hernias

The common sites for herniation of viscera through the diaphragm are shown in Fig. 46.3.

#### Hiatus hernia

Herniation through the oesophageal hiatus is the most common type of diaphragmatic hernia. It is not considered in detail here but is mentioned because it may present on a chest film as a retrocardiac opacity containing a fluid level (Fig. 46.4). The uninitiated may mistakenly diagnose a lung abscess or cyst.

#### Bochdalek hernia

Bochdalek [128] first described the embryology and the congenital absence of the posterolateral part of the diaphragm in 1848. This is the most common site for congenital diaphragmatic hernia and an incidence of 0.8 per 1000 live births has been reported [129]. The foramen of

**Fig. 46.2** Posteroanterior (a) and lateral (b) chest films showing partial eventration of the right hemidiaphragm anteriorly.

(a)

(b)

**Fig. 46.3** Diaphragm viewed from above showing sites of possible herniation. Thick lines show most common sites.

Bochdalek is normally closed by the eighth week of fetal life. Failure of the pleuroperitoneal membrane to fuse with the septum transversum allows herniation of the abdominal contents into the hemithorax; 75% occur on the left and there may be other associated malformations, most commonly of the central nervous system [130]. A 13th pair of ribs is a reported association [131]. The lung on the side of hernia is usually hypoplastic with a reduction in the number of airway generations, although normal numbers of alveoli are found in the segments that are present [132,133]. The contralateral lung may also be hypoplastic and this heralds a poor prognosis [133,134]. In an extreme form, Bochdalek hernia merges with congenital diaphragmatic agenesis, a condition more readily diagnosed by antenatal ultrasound but which causes even more severe postnatal respiratory problems [135].

#### *Clinical presentation*

The majority present soon after birth with respiratory distress. A scaphoid abdomen is usually noted. Radiographically the diaphragm is not seen on the affected side and loops of intestine are found in the thorax, with displacement of the mediastinum. There is a relative absence of gas in the abdomen. Herniation on the right is less likely to be life-threatening, perhaps because the liver blocks the defect. While a right-sided hernia may occasionally present with respiratory distress, asymptomatic presentation with an intrathoracic mass of liver or bowel is more common [136,137].

Presentation in adulthood is uncommon. In a review of

50 cases in 1971, one-quarter were asymptomatic while the remainder presented with abdominal pain or vague remitting gastrointestinal symptoms with or without obstruction [138]. Delayed presentation following a previously normal chest film may occur [139].

#### *Management and prognosis*

Management of patients in respiratory distress is with ventilatory support and correction of acidosis, followed immediately by surgical repair, either by direct suture or with insertion of synthetic patches [140]. Contralateral pneumothorax may occur postoperatively due to the high inflation pressures required, and prophylactic pleural intubation has been employed by some [130,141].

Overall survival rates of 70–80% have been reported in neonates, with lower rates in those requiring operation within the first 24 h of life [142,143]. The majority of deaths are due to the presence of severely hypoplastic lungs that are incapable of sustaining life. In those with unilateral hypoplasia, compensatory emphysema may develop in the other lung [132].

#### *Morgagni hernia*

The foramen of Morgagni lies anteromedially and is bounded anteriorly by the sternum, medially by the sternal portion of the diaphragm and laterally by the costal portion of the diaphragm in the region of the attachment to the seventh costal cartilage. It is usually filled with loose connective tissue but omentum, colon, liver or other infradiaphragmatic structures, including gallbladder, may herniate through the foramen, more commonly on the right [144].

#### *Clinical presentation*

Presentation in childhood is rare, although Morgagni hernia has been reported as a cause of intermittent cyanotic attacks in an infant [145]. Where symptoms are present, feelings of pressure, tightness, fullness or pain in the right anterior chest occasionally with referral to the shoulder tip are admitted [146]. Strangulation of the bowel may occur.

The chest film shows a rounded density in the cardiophrenic angle that may or may not contain gas (Fig. 46.5). Barium studies determine the presence of intestine, and in the case of an omental hernia the transverse colon is hitched up. Pneumoperitoneum may be needed to make a definitive diagnosis.

#### *Management*

Surgical repair by suture after reduction of the hernia is normally sufficient.

**Fig. 46.4** (a) Solid lesion with indistinct air-fluid level behind heart. (b) Lateral view shows it to be a hiatus hernia.

(b)

**Fig. 46.5** Posteroanterior (a) and lateral (b) chest films showing Morgagni hernia. This 68-year-old patient presented with increasing dyspnoea.

(a)

(b)

**Fig. 46.6** Traumatic hernia. Posteroanterior (a) and lateral (b) chest films taken in 1987 of a 67-year-old man who suffered a shrapnel wound in Normandy in 1942 that necessitated splenectomy. No diaphragmatic lesion was noted at that time and it was not until 1958 that colon was seen in the chest on a routine chest film. No action was taken and the patient remains asymptomatic. Presumably the diaphragm was lacerated or ruptured by shrapnel in 1942.

### Traumatic hernia

Traumatic diaphragmatic hernias are most commonly seen following blunt non-penetrating trauma to the chest in road traffic accidents or falls from a height. Many are detected at the time of the initial injury although a substantial number present later, even up to 15 years after the initial injury [147] (Fig. 46.6). It has been estimated that 90% of traumatic diaphragmatic hernias are overlooked at the time of injury [148].

Traumatic hernias represent only 5% of all diaphragmatic hernias, but 90% of all strangulated hernias result from trauma [149]; 90% of tears occur in the left leaf of the diaphragm, most commonly in the central and posterior portion. The most common hernial contents are omentum, stomach or colon, although any abdominal organ including kidney may be found. Rarely, herniation into the pericardium occurs [150–152].

### Clinical presentation

The most common complaints are of upper abdominal or lower chest pain with dyspnoea, which may be worse after eating [147,148]. Bowel sounds may be audible in the chest. If strangulation occurs, sudden and progressive severe lower chest or upper abdominal pain is experienced, with dyspnoea, vomiting or retching. Upper

abdominal guarding is found and progression to shock occurs [153,154]. On one occasion, the author has seen perforation of colon into the pleura following traumatic rupture of the diaphragm, causing pyopneumothorax. A rare complication of traumatic rupture is bronchopancratic fistula following acute pancreatitis; this can be diagnosed by finding high levels of amylase in the profuse frothy sputum [155].

### Radiology

Radiologically, the only evidence may be an elevated hemidiaphragm; at the other extreme multiple air–fluid levels may be present. Barium studies demonstrate obstruction or constriction of the stomach or colon as it passes through the tear [149]. With herniation of the liver on the right side, pneumoperitoneum (which results in pneumothorax) may be needed to confirm the diagnosis. CT may enable the discontinuity in the diaphragm to be seen [156].

### Management

Surgical repair may be achieved by the abdominal, thoracic or combined routes [148]. In view of the common concurrence of injury to abdominal viscera, the abdominal route is usually preferred [157].

# SLEEP APNOEA/HYPOPNOEA SYNDROME

NEIL J. DOUGLAS

The sleep apnoea/hypopnoea syndrome is probably the most common medical disorder to be described in the second half of the twentieth century. It is not a new condition, merely a recently recognized one, as cases can be identified from manuscripts thousands of years old [1,2]. One of the earliest reports in the British medical literature was in 1829 when Wadd [3] reported a man who 'weighed 23 stone . . . and was withal so lethargic that he frequently fell asleep in company. He felt much inconvenienced and alarmed . . . and was sent to Edinburgh to consult Dr Gregory. He reduced himself to 15 stones . . . he is now well'. Joe, the fat boy in Dickens' *Posthumous Papers of the Pickwick Club* [4] made his appearance in 1837 and is testimony to Dickens' powers of observation, powers that exceeded those of most of his physician contemporaries or indeed those of physicians over the next century and a half. Joe was described as being obese, catastrophically sleepy, of ruddy complexion and having the dropsy (right heart failure).

The medical discovery of sleep apnoea occurred simultaneously in Germany and France in 1965 [5,6]. Both groups recorded physiological variables overnight and recognized the association between breathing pauses during sleep and daytime sleepiness, thus describing the condition that became known as the sleep apnoea syndrome [7]. Interest in the condition spread to North America and Australia and thereafter gradually to the rest of the world. With the identification of episodes of marked hypoventilation (hypopnoeas) during sleep not sufficiently severe to be true apnoeas but which have similar consequences [8], the condition has subsequently become known in many centres as the sleep apnoea/hypopnoea syndrome (SAHS).

## Epidemiology

Over the past few years, prevalence studies have been performed in different countries and continents using different techniques. However, their conclusions have been broadly similar, namely that SAHS occurs in 2–6% of

middle-aged men and 1–2% of middle-aged women [9–12].

Jennum and Sjol [12] randomly selected 2000 Danish citizens in the age group 30–60 years, of whom 1504 responded. Half the respondents were randomly selected for study of their breathing pattern overnight; 10.9% of the men and 6.3% of the women were found to have more than five apnoeas plus hypopnoeas per hour of sleep, while 1.9% of the men and 0.9% of the women had the same degree of abnormal breathing during sleep and also daytime sleepiness in socially unacceptable conditions.

Young and colleagues [9] studied a random sample of 602 employed men and women aged 30–60 years from Wisconsin using overnight polysomnography (the recording of sleep pattern from the EEG plus breathing and oxygenation patterns) in order to determine the frequency of irregular breathing during sleep; 9% of the women and 24% of the men had more than five apnoeas plus hypopnoeas per hour of sleep, whereas 2% of women and 4% of men had this degree of abnormal breathing during sleep plus daytime sleepiness. The methodology used in the study, including sampling techniques and the performance of overnight polysomnography, make this probably the most robust of the epidemiological studies, although the population studied may be more obese than is the norm in some countries.

Bearpark and colleagues [10] reported that 26% of 294 Australian men had more than five apnoeas plus hypopnoeas per hour in bed, with 3% having the same degree of breathing irregularity plus daytime sleepiness. Olson and colleagues [11], also from Australia, reported that at least 5.7% of middle-aged men and 1.2% of middle-aged women had more than 15 apnoeas plus hypopnoeas per hour of sleep but did not quote data for the coexistence of sleepiness.

With a prevalence of around 2–6% in the middle-aged, sleep apnoea thus has a similar frequency to symptomatic asthma or to diabetes in the same age group. This high prevalence, in conjunction with the significant associated morbidity, has led to the suggestion that it 'has an impact

on society that rivals that of smoking' [13]. Although the epidemiology is best documented in the middle-aged, sleep apnoea also occurs in children and the elderly but the precise prevalences are not yet clear.

### Mechanisms of upper airway narrowing

SAHS results from recurrent narrowing of the supraglottic airway during sleep. The patency of the pharynx depends upon a balance between transmural pressure and upper airway muscle activity (Fig. 47.1). During inspiration, the negative intraluminal pressure tends to narrow the upper airway and this is opposed by the action of upper airway dilating muscles. These muscles tense with each inspiration, thus resisting collapse of the upper airways and probably also stiffening the airway and so preventing vibration. The principal muscles involved are genioglossus, which tenses the tongue, and palatoglossus, which holds the soft palate in the downwards and forwards position thus resisting collapse of the nasopharynx (Fig. 47.2). Other palatal muscles, including palatopharyngeus, are also involved and there is some evidence to suggest that generalized tensing of palatal muscles, whatever their direction of action, results in palatal stiffening that resists upper airway collapse.

Muscle tone decreases throughout the body during sleep and the relaxation of the upper airway dilating muscles results in relative narrowing of the pharynx. In normal subjects, this narrowing results in increased airflow resistance that is of no major significance [14]. However, in about 50% of middle-aged men and 30% of middle-aged women, this upper airway narrowing is sufficient to cause marked turbulent flow with the associated vibration of snoring. In some, this tendency may progress to produce clinically significant upper airway narrowing or occlusion sufficient to cause sleep disruption and thus clinical sequelae.

The site of airway narrowing during sleep is usually at the retropalatal or retroglottal level [15,16]. In many patients, the occluded segment spans both the retropalatal and retroglottal segments and this probably explains why

surgical approaches designed to increase airway calibre in only one of these locations are frequently unsuccessful.

### Upper airway

Patients with SAHS tend to have narrower upper airways when awake than either normal subjects or simple snorers; however, there is substantial overlap between the groups [17–19]. There is considerable evidence indicating that anatomical factors contribute to this upper airway narrowing. Patients with SAHS have increased deposition of adipose tissue around their upper airway, particularly lateral to the pharynx [20,21]. This increased fat deposition is found in obese patients with SAHS compared with obese controls [20] and also in non-obese patients with SAHS compared with non-obese controls [21] (Fig. 47.3).

### Bony structure

Some patients with SAHS have abnormal facial bony structure [18,23,24]. The most common abnormalities are small maxillae and mandibles, with resulting retrognathia. The anteroposterior shortening of the face produces narrowing of the upper airway [18,24,25]. These abnormalities are more common in non-obese patients with SAHS [24]. The abnormalities may be familial, although it is not yet clear whether they are inherited or environmental [25].

### Physiological factors

It is difficult to test whether there are abnormalities of neuromuscular control in patients with sleep apnoea compared with normal subjects. Many studies have shown that the upper airway in patients with SAHS is more liable to collapse during both wakefulness and sleep [26–28], although this may be due to anatomical factors. Some studies [29], but not all [30], have indicated that there is

Fig. 47.1 Schematic diagram of upper airway physiology.

Fig. 47.2 Actions of upper airway dilator muscles.

**Fig. 47.3** Magnetic resonance images of a normal subject (a) and a patient of similar age and weight with the sleep apnoea/hypopnoea syndrome (b). The black area in the centre of each image is the upper airway, which is smaller in the patient

with sleep apnoea compared with the normal subject even during the awake scans. The white areas lateral to the upper airway in the patient with sleep apnoea/hypopnoea syndrome represent adipose tissue. (From Douglas [22] with permission.)

increased activity of the upper airway dilating muscles in awake patients with SAHS compared with controls, suggesting that patients need to defend their upper airways to keep them patent. This might therefore be a secondary response to anatomical narrowing. Upper airway muscles tense in a reflex response to negative upper airway pressure and Mortimore and Douglas [31] have recently compared this response in normal subjects and in patients with SAHS, finding that the latter have an impaired response to negative upper airway pressure. This suggests that there may be physiological as well as anatomical abnormalities in SAHS.

Sleep induces hypotonia of the upper airway dilating muscles. This is associated with both decreased and delayed responses to negative pressure [32]. These changes thus predispose to upper airway narrowing and occlusion. However, it is not yet clear whether the decrease in upper airway muscle activity and force generation differs between patients with SAHS and normal subjects.

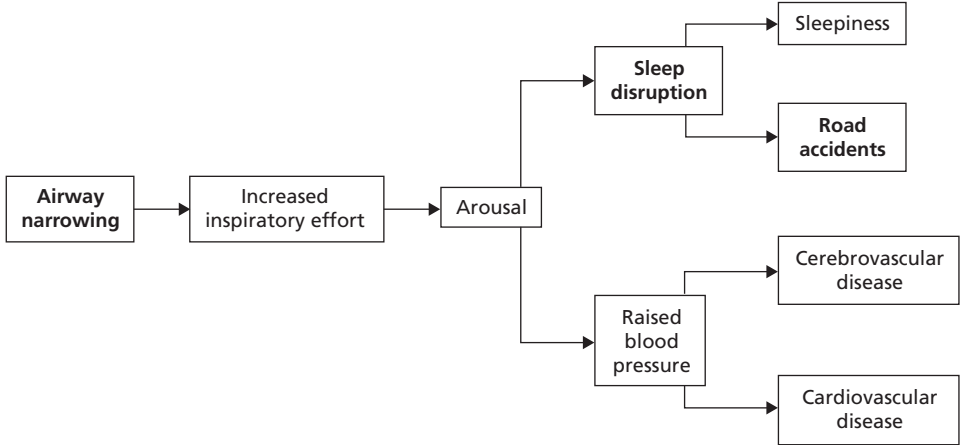

### Consequences of upper airway narrowing

Upper airway narrowing results in a compensatory increase in respiratory effort in an attempt to maintain ventilation. This increase in respiratory effort is the under-

lying trigger that stimulates arousal from sleep [33]. It was initially thought that total airway occlusion and cessation of ventilation were required for the pathophysiological sequelae to develop; it was later realized that continued, although diminished, ventilation in the form of hypopnoeas produced identical consequences [8]. There is now evidence that increased upper airways resistance in the absence of a diminution in ventilation may also produce identical sequelae [34,35]. These arousals restore upper airway dilating muscle activity, the patient gasps, takes a few deep breaths and then falls back to sleep, at which point the upper airway dilating muscles relax again and the cycle is initiated once more. These episodes of upper airway narrowing terminated by arousal may recur many hundreds of times per night and the recurrent arousals are thought to cause the major clinical features of the condition (Fig. 47.4).

The frequency of brief arousals from sleep correlates significantly with the impairment in daytime performance found in SAHS. Specifically, arousal frequency is correlated with reaction time and with the decrease in IQ observed [37]. Further evidence that it is sleep disruption which causes symptoms in SAHS come from modelling experiments in which normal subjects have been woken very briefly repeatedly through the night without any overall change in sleep duration. In these studies, recurrent arousals produce objective and subjective daytime

**Fig. 47.4** Mechanism and consequences of arousal following airway narrowing. (From Douglas & Polo [36] with permission.)

sleepiness and impaired daytime cognitive performance of the type found in SAHS [38].

Each arousal causes a transient rise in systemic blood pressure [39], the magnitude of which may vary from a small increase to a doubling of both systolic and diastolic pressures. These blood pressure rises may occur even when there are no visually discernible features of arousal on the EEG. Such repeated elevations of blood pressure hundreds of times per night over years or decades presumably account for the reported increase in morbidity and mortality from cardiovascular and cerebrovascular disease in patients with SAHS [40].

**Clinical features**

**Symptoms**

The patient’s major complaints are usually daytime sleepiness and unrefreshing nocturnal sleep (Table 47.1). Sleepiness must be differentiated from physical fatigue since both tend to be described as ‘tiredness’. Many patients admit to falling asleep at least once a day when not in bed [41] and many have been troubled by sleepiness for years prior to presentation. Sleep attacks can occur at any time of day but are usually worst in the early afternoon and evening, coincident with the circadian tendencies to sleepiness in the normal population. The urge to sleep usually comes on gradually but sometimes may be rapid and is often irresistible. Initially, sleepiness tends to present only during monotonous activities, classically watching television in the evening or during unstimulating driving such as on motorways or freeways. As sleepiness becomes more severe, it intrudes progressively into daily activities until sleep intervenes during all varieties of driving, when operating machinery or during conversations and meals. Some patients deny daytime sleepiness but report that they have impaired concentration that causes significant deterioration in their work performance.

**Table 47.1** Symptoms of the sleep apnoea/hypopnoea syndrome.

<i>Reported by patient</i>
Sleepiness
Poor concentration
Difficulty driving long distances
Unrefreshing sleep
Morning lethargy
Sleep-related choking/dyspnoea
Nocturia
Decreased sex drive
<i>Reported by partner</i>
Snoring: intermittent, loud
Apnoeas
Irritability

Most patients with SAHS find nocturnal sleep unsatisfying, usually waking up feeling as if they have not had a good night’s sleep. However, most do not report an increased frequency of nocturnal awakenings. Approximately one-third of patients have intermittent nocturnal choking attacks related to upper airways obstruction. Usually these are occasional but often terrifying events.

Nocturia is common and often troublesome. It is due to increased salt and water excretion at night [42] and ceases with adequate therapy. Young men with SAHS may complain of loss of libido and impotence. A few patients have reported automatic behaviour and disorientation after awakening, although many more report that they have difficulty getting started in the morning. Ankle oedema is reported by a minority, most of whom have coexisting respiratory disease [43,44], presumably because they have two causes for nocturnal hypoxaemia and thus have more severe hypoxaemia and therefore more marked sequelae.

Most spouses of patients with SAHS report that the patient is a loud snorer and often that their snoring is

intermittent, punctuated by multiple apnoeas. However, such a story cannot always be obtained, either because the patient does not have a bed partner or because these features have not been observed by a partner who is usually asleep. Normally, the patient has snored loudly for many years and snores in all body postures. Bed partners also report restless sleep as the patient fights for breath, the bedclothes often being rearranged. Partners may also report psychological changes, particularly irritability or depression.

### **Patient characteristics**

Around 80% of patients with SAHS are male [41]; the reason for this is not clear, although it relates to testosterone in some way since this can induce SAHS in hypogonadal men or in women [45–47]. Males have a central pattern of obesity and this produces greater deposition of fat in the neck of men than women. This may result in greater mass loading of the upper airway on lying down. Around 50% of patients with SAHS are obese. However, an increasing number of patients with SAHS are now found to have normal body weight, with more than 50% of our new patients having a body mass index of less than 30 kg/m<sup>2</sup> and some less than 20 kg/m<sup>2</sup>.

Most patients are middle-aged, although the reasons for this are unclear. Upper airway calibre has been found to narrow with age in awake men in some studies [48] but not all [49]. However, age has been found not to affect upper airway calibre in awake women [48].

All affected individuals should be examined for abnormalities of the nose or oropharynx. In some centres, all patients are seen by an otorhinolaryngological surgeon but in others this is reserved for selected patients with appropriate symptoms or abnormal findings on gross examination. Enlarged tonsils are a common cause of sleep apnoea in children and an occasional cause in adults and must be excluded by oropharyngeal examination. Other medical conditions that must be considered include hypothyroidism, acromegaly, Marfan's syndrome and upper airway tumours. Gross retrognathia is relatively uncommon but since it is a correctable cause it should always be sought.

## **Consequences of sleep apnoea**

### **Death**

Early data suggested that sleep apnoea was associated with increased mortality [40,50]. Later studies have not found any clear increase in mortality in patients with SAHS when allowance is made for coexisting risk factors such as obesity, smoking and age [51]. However, larger and better-designed studies are required before this issue can be satisfactorily resolved.

### **Road traffic accidents**

Many patients with SAHS report falling asleep at the wheel and some have road traffic accidents as a consequence. There is convincing evidence that members of the population with irregular breathing during sleep [52] and patients with SAHS have an increased frequency of road traffic accidents [53–55]. The overall increase in frequency is around two- to four-fold, although there may be a nine-fold increase in single-vehicle accidents, i.e. the type of accident typically caused by drivers falling asleep at the wheel [55]. Not only are these accidents common but they are also dangerous. Falling asleep at the wheel accounts for 15–20% of road traffic accidents and these sleep-related accidents are associated with an increased morbidity [56]. Indeed, a recent study in Bavaria has suggested that falling asleep at the wheel is the most common cause of fatal road accidents, and specifically caused more fatal accidents than alcohol [57]. Driving simulator studies show that untreated patients with sleep apnoea drive worse than normal subjects made legally drunk [58]. Obviously, sleep apnoea is only one of several causes of sleep-related road accidents and general fatigue may be more common. Patients with SAHS often report that they have no problems driving short distances in town or on minor roads where sensory input is fairly high but have great difficulties driving on motorways or freeways where the monotonous conditions predispose to sleep. Patients with sleep apnoea also underreport the severity of their driving impairment prior to receiving treatment [59].

### **Hypertension**

Many studies have attempted to assess whether there is an increased frequency of systemic hypertension in SAHS. Assessment of the significance of the differences observed is made difficult by the need to allow for potentially confounding factors, including obesity, age, smoking and alcohol consumption. Furthermore, some of the studies have used methods of diagnosing sleep apnoea that are not sufficiently precise by present-day criteria. Several studies have also used single measurements or even retrospective measurements of blood pressure rather than repeated measurements or 24-h recording. Others have studied patients on antihypertensive therapy, which may affect not only blood pressure but also, perhaps, nocturnal breathing pattern. Few studies stand up to rigorous review of their methodological standards.

Hla and colleagues [60] found an increased frequency of hypertension during 24-h monitoring in patients with SAHS compared with either snoring or non-snoring normal subjects. These differences persisted after controlling for age, sex and obesity. In a recent study, the same group have reported that blood pressure is correlated with

frequency of apnoea/hypopnoea and that even individuals with five apnoeas plus hypopnoeas per hour have a higher blood pressure than those with none, again when controlling for other variables [61]. This strongly suggests that irregular breathing at night produces clinically important effects on blood pressure that persist even after controlling for other risk factors. Other population-based studies have also found significant relationships between SAHS and hypertension, although these were explained by associations between hypertension and sex, age, body mass and alcohol consumption [62,63]; in both these studies blood pressure was only recorded on one occasion. Whether or not the 24-h blood pressure is significantly raised in patients with SAHS, there is no doubt that patients have hundreds of transient elevations of blood pressure every night associated with each arousal from a respiratory event [39]. Recurring every night for years or even decades, these could produce significant cardiovascular and cerebrovascular sequelae even in the absence of daytime hypertension.

### **Cardiovascular risk**

A retrospective study has shown that patients with myocardial infarction have a raised frequency of apnoeas during sleep [64]. A population-based study of 441 middle-aged subjects has indicated that patients with irregular breathing at night have a 3.5-fold increased risk of coronary artery disease; however, when adjustment was made for age, sex, body mass index, alcohol consumption and smoking, this ratio decreased to a non-significant 1.4 (95% confidence interval 0.4–3.5) [63]. Thus, the relationship between sleep apnoea and ischaemic heart disease is not yet clear.

### **Cerebrovascular disease**

Several studies have shown associations between snoring and cerebrovascular disease [65–68] and these findings persist after correction for age, smoking and obesity, although there are no data indicating whether SAHS *per se* predisposes to cerebrovascular accidents. However, there is evidence from a retrospective study that treatment for sleep apnoea decreases 'vascular' mortality, i.e. a combination of cerebrovascular and cardiovascular death [40]. Data suggest that the severity of snoring prior to a cerebrovascular accident is a predictor of outcome [68], indicating that nocturnal breathing may be important in the pathogenesis of cerebrovascular accidents.

### **Right heart failure/respiratory failure**

The development of chronic carbon dioxide retention, pulmonary hypertension and peripheral oedema in SAHS

usually requires an additional respiratory problem, most commonly chronic airflow obstruction [43,44,69]. Occasionally, other coexisting respiratory problems, such as extreme obesity or weakness of the respiratory muscles, may also produce these complications.

### **Sudden infant death syndrome**

There appears to be an increased frequency of sudden infant death syndrome (cot deaths) in the families of patients with SAHS [70,71]. This observation was made in the families of non-obese patients with SAHS. Families who had both SAHS and sudden infant death syndrome had retroposition of the maxilla and mandibles. A recent study indicates that victims of sudden infant death syndrome also have retroposed maxilla in comparison to age-matched control infants [72]. It is not yet clear how many, if any, cases of sudden infant death syndrome result from an SAHS-related mechanism.

### **Differential diagnosis**

Other causes of daytime sleepiness need to be considered [73].

### **Narcolepsy**

Narcolepsy occurs in 0.05% of the population and thus has a frequency about one-hundredth that of SAHS. Narcolepsy tends to present at 10–30 years of age, whereas patients with SAHS tend to present in middle age. The four characteristic features of narcolepsy are daytime sleepiness, cataplexy, hypnagogic hallucinations and sleep paralysis.

Cataplexy is the sudden onset of muscle weakness when awake, almost always in response to amusement or some other strong emotion. It can vary between minor drooping of the head to total collapse. Hypnagogic hallucinations are vivid dreams at the onset of sleep and both these and sleep paralysis relate to the propensity for REM sleep suffered by these patients.

The diagnosis of narcolepsy is easy when sleepiness is associated with one of the other features of the tetrad but it commonly is not, in which case the demonstration of sleep-onset REM during multiple sleep latency testing [74] and the demonstration of HLA-DR2, DQw1 may be helpful as may a family history, although the latter is by no means always positive. Narcolepsy is best treated by a combination of simple advice (e.g. taking postprandial naps where possible, and avoiding dangerous situations if feasible) and stimulant medication. Drugs normally used include mazindol, methylphenidate, dexamfetamine (dexamphetamine) and modafinil. Tolerance to these drugs may develop and drug holidays may be required. Cataplexy can also be difficult to treat but drugs of

choice include clomipramine, imipramine, fluoxetine and phenelzine.

### **Idiopathic hypersomnolence**

Nocturnal sleep duration tends to be longer than usual and daytime naps are also longer than those found in sleep apnoea or narcolepsy, often lasting over 1 h. The morning is often the worst time of day for patients with idiopathic hypersomnolence, with morning drunkenness as a troublesome feature for some. Like narcolepsy, this condition usually presents first at 10–30 years of age, earlier than SAHS. Treatment is the same as with narcolepsy in terms of advice and stimulant drugs.

### **Periodic limb movement disorder**

Repetitive leg movements occur in many individuals during sleep, perhaps up to 30% by the age of 60 years. These leg movements occur around every 20 s during non-REM sleep but usually disappear totally during REM sleep. When these leg movements are followed by arousals, they may cause daytime sleepiness and treatment with either L-dopa or a benzodiazepine can be beneficial.

### **Post-traumatic hypersomnolence**

Persisting daytime sleepiness following head injury is well documented. This may also occur following cranial surgery or a cerebrovascular accident.

### **Kleine–Levin syndrome**

This rare syndrome causes recurrent episodes of hypersomnolence lasting several days or weeks at a time and recurring perhaps once or twice a year. The patient is often an adolescent and the episodes of prolonged sleeping may be associated with bouts of binge eating and hypersexual activity. Usually the condition gradually improves with time. Lithium therapy may be helpful.

### **Psychiatric illness**

Severe depression and psychotic illnesses may be associated with daytime sleepiness. Psychiatric referral should be considered for not only sleepy patients with overt psychiatric illness but also those in whom no medical cause for sleepiness can be found.

### **Psychological sleepiness**

Occasional daytime sleepiness may relate to anxiety or depression. More often these conditions are associated with insomnia rather than sleepiness.

### **Insufficient sleep**

Patients should always be asked about their normal sleep duration. Prospective sleep diaries may be helpful in this situation.

### **Shift work**

It can be very difficult to ascertain whether the patient's shift rota itself is causing the reported sleepiness and an accurate history is essential.

### **Drug abuse**

Hypnotics, sedatives and alcohol in excess can all cause sleepiness. Trials of withdrawal may prove helpful.

## **Diagnosis**

### **History and examination**

The diagnosis of SAHS cannot be adequately made from the history alone. While questions about intensity of snoring, witnessed apnoeas and falling asleep while driving are useful for selecting patients likely to have SAHS from the general population [75], they are of less value in patients presenting to a sleep clinic, many of whom have such symptoms. Several studies have attempted to distinguish which of the patients presenting to a sleep clinic may have SAHS on history alone but the results have been disappointing. Factors increasing the likelihood of sleep apnoea are witnessed apnoeas [76–78], nocturnal choking [76,77], sleepiness [78], being male [76,77], obesity [76–78], hypertension [77] and the presence of a narrowed pharynx with a large uvula [76]. However, none of these are sufficiently specific to be diagnostically useful, the most helpful being the presence of witnessed apnoeas in 75% of patients with SAHS; however, apnoeas are also reported in around 60% of patients referred to sleep clinics who are shown not to have SAHS [76,77]. Predictive equations can be built around these observations but their value in limiting the number of sleep studies required has yet to be proved.

### **Sleep studies**

The 'gold standard' for the diagnosis of SAHS was originally thought to be polysomnography, which involves the overnight recording of sleep, breathing patterns and oxygenation (Table 47.2). However, the need for this level of investigation in all cases and the associated expense has been questioned as a result of the limitation of healthcare budgets combined with the rapidly increasing numbers of patients being referred for investigation.

**Table 47.2** Variables recorder during polysomnography.

<i>Usual</i>
Neurophysiology
EEG
Electro-oculography
Electromyography: submental, anteriotibial

Blood pressure
Penile tumescence
Light intensity

The recording of sleep quality and duration appears to play little part in the routine clinical diagnosis of SAHS according to a study of 200 patients [79]. The re-examination of patients who either slept for less than 3 h per night or who had no REM sleep did not change the clinical diagnosis, and the identification of early REM sleep was also not diagnostically useful. The expense of sleep recording does not therefore appear to be justified in routine studies. However, there are occasional patients who genuinely do not sleep during either diagnostic or therapeutic sleep studies. Thus, if a technique is used that does not record sleep and the patient indicates that sleep was very poor, polysomnography should be considered to allow interpretation of the breathing pattern during sleep.

The major value of recording sleep may be to identify transient arousals; however, there is no agreement on the definition of such brief arousals [37,80]. Furthermore, even this may not be a reason for recording EEG, since arousals may be better detected by examining changes in cardiovascular or respiratory pattern. For example, each arousal is associated with a rise in blood pressure [81] and a shortening in pulse transit time [82] and most are associated with an increase in tidal volume and with the loss of flow limitation.

Many different respiratory sensors have been used to detect SAHS, including oximetry, airflow signals, thoracoabdominal movement, snoring detectors and oesophageal pressure. Oximetry alone can detect about two-thirds of patients with SAHS and this is best done by a trained observer examining the pattern of desaturation [79,83]. Current computerized systems designed to detect recurrent desaturations are highly specific when positive (specificity 97–100%) but are not adequately sensitive (sensitivity 30–40%). Thus, oximetry alone can be diagnos-

tic when positive although normal oximetry by no means excludes the diagnosis of sleep apnoea nor indeed can it even exclude severe sleep apnoea. It must be remembered that the magnitude of daytime impairment in patients with SAHS in terms of reaction time and driving ability relates to arousal frequency more than the degree of desaturation [37]. Thus, patients with recurrent respiratory-associated arousals who have either SAHS or the so-called upper airways resistance syndrome may show no desaturation during sleep but have severe symptoms and benefit greatly from continuous positive airway pressure (CPAP) or other treatment. These limitations of oximetry must be realized by those using this technique either on its own or as a key component in their diagnostic systems.

SAHS was initially diagnosed from recurrent episodes of flow cessation. More recently, it has been realized that events in which there is continued airflow but reduced thoracoabdominal movement (hypopnoeas) are also associated with recurrent arousals and similar clinical sequelae [8]. Indeed, even hypoventilation may not be necessary for the clinical features of the syndrome, some patients exhibiting repeated arousal following increases in upper airways resistance with no decrease in ventilation (upper airways resistance syndrome) [34,35]. There is widespread confusion about this terminology, with similar patients being diagnosed in some centres as having hypopnoeas, in others partial airways obstruction and in yet others upper airways resistance syndrome. This is of more than semantic importance since if upper airways resistance-induced arousals in the absence of any change in ventilatory pattern are common, then the diagnostic strategy must centre on proving the coincidence of an arousal with some relatively subtle respiratory change. These respiratory changes may be documented by invasive techniques such as oesophageal pressure along with EEG monitoring, or less invasively by detecting inspiratory flow limitation or changes in thoracoabdominal phase angle, or by using the static charge-sensitive bed.

There are many different techniques used to record thoracoabdominal movement, including inductance plethysmography, impedance pneumography, strain gauges, piezoelectric systems or charge-sensitive beds. Each gives different results and all users must be aware of the advantages and disadvantages of their system. Thoracoabdominal movement can be used to classify apnoeas into central or obstructive, although this may not be a useful classification since many apnoeas labelled as 'central' respond to CPAP [84]. This may be because the events are initiated with upper airway occlusion, which reflexly inhibits subsequent ventilatory efforts, or because relatively poor thoracoabdominal signals are obtained from some individuals, particularly the grossly obese. The rare true central apnoea can only be diagnosed by oesophageal manometry or respiratory muscle electromyography.

The major use of the thoracoabdominal signal is to identify hypopnoeas, which are better defined with inductance plethysmography than conventional flow sensors since temperature-based measurements do not provide a quantitative estimation of ventilation, there being little difference between the temperature of an expired volume of 100 mL and that of 1000 mL [8]. The conventionally used flow-based devices that record temperature, expired  $P_{CO_2}$  or tracheal sound are adequate to detect true apnoeas, although such apnoeas are detected adequately by inductance plethysmography and thus the need for a flow signal is unclear [85]. Flow signals based on true flow-measuring devices such as pneumotachographs or on the measurement of intranasal pressure may allow detection not only of apnoeas and hypopnoeas but also of flow limitation, thus providing a non-invasive method of diagnosing upper airways resistance syndrome [86]. This is an area of considerable research.

Many different devices have been developed to record snoring. However, the sensitivity of these for diagnosing SAHS based on snoring alone has been poor (around 27%), although specificity is high [87]. Thus, at present, these devices on their own cannot be recommended for excluding SAHS, although the addition of other monitors such as oxygen saturation greatly improves their diagnostic value [88].

There is a confusing array of limited sleep study devices that use various combinations of the above sensors. Unfortunately, most systems are poorly validated at present. It is imperative that the users of such equipment fully appreciate the potential for false-positive and false-negative results with their own system.

Ideally, all sleep studies should have the ability to detect the periodic limb movements found in at least 5% of patients referred to a respiratory sleep clinic [79]. These patients may benefit from treatment for this condition. Such limb movement can be detected either by electromyography, the classical method, or by piezoelectric, static charge bed or video techniques.

### Diagnostic strategy

Many factors determine the diagnostic strategy, including the availability of resources and equipment and the distances travelled by patients. Few centres can afford the luxury of polysomnography for all patients referred; indeed, it is not required for the clinical management of most patients. The diagnostic approach depends upon the patient's presenting features and in the author's view the following approach is reasonable.

#### Patients highly likely to have sleep apnoea

Patients who fall asleep at least once a day when not in bed, are loud snorers with witnessed apnoeas and have no

features to suggest periodic limb movement disorder or narcolepsy should have a limited sleep study performed either at home or in hospital without EEG documentation of sleep being obtained. If this overnight study is unequivocally positive, the patient may proceed to therapy but a negative study must result in further investigation.

#### Simple snorers with no features of sleep apnoea

Any patient who is considering dental splinting or surgery for snoring should have a limited overnight sleep study, which includes recording of snoring so that both the presence of snoring and the presence or absence of sleep apnoea can be documented. In some patients, several nights' recording of snoring may be required to establish whether there is a major problem warranting surgery, as many alleged 'habitual snorers' are found to snore rarely.

#### Patients with moderate likelihood of sleep apnoea

Our practice in such patients depends on their proximity to the sleep laboratory. Those living less than 80 km away have a limited sleep study performed at home. This saves time and money, although a conservative definition of abnormality has to be used since events occurring during wakefulness are included in the analysis and sensitivity and specificity may differ from that used during polysomnography [89]. Those living more than 80 km away tend to find it inconvenient to travel to and from the sleep laboratory twice in order to collect and return the equipment and overnight sleep studies in the laboratory are more satisfactory. As the costs of a hospital bed are incurred, it is imperative that the maximal amount of diagnostic information is obtained on this night and it is the author's practice therefore to perform overnight polysomnography on all patients living more than 80 km away who give a reasonable but not totally convincing story of SAHS. This stance may change with the development of better limited sleep study equipment.

#### Patients who may have other diagnoses

In patients with significant daytime sleepiness without obvious drug or psychological cause and who do not have a good history of SAHS, it is reasonable to perform overnight polysomnography, perhaps combined with the daytime multiple sleep latency test both to quantify the severity of the daytime sleepiness and to help with the diagnosis of narcolepsy through the documentation of early REM sleep [74].

This scheme is just one of many and will require modification as diagnostic equipment becomes more sophisticated and better suited to home use. It supposes access to limited sleep study equipment capable of measuring

breathing pattern, snoring, oxygenation and leg movement in each hospital. It is reasonable for hospitals without such facilities to use oximetry for patients with a high probability of having SAHS since it is positive in two-thirds of patients with SAHS and a positive result allows rapid initiation of CPAP. However, all patients with negative or equivocal oximetry alone need to be referred for further investigation.

## Treatment

The threshold for benefit from treatment has yet to be established. Most patients with more than 15 apnoeas plus hypopnoeas per hour of sleep who are troubled by daytime sleepiness benefit from therapy [90]. However, there are a significant number of patients with fewer events who are troubled by daytime symptoms who also benefit from therapy [91]. At present, the author's policy is to offer treatment to all those with troublesome sleepiness who have more than 15 apnoeas plus hypopnoeas per hour of sleep or more than 15 respiratory-related arousals per hour in the context of the upper airways resistance syndrome.

All such patients should receive advice on weight reduction and alcohol avoidance as routine. Those with otorhinolaryngological symptoms or abnormal findings on examination should be referred in order to discover whether improvement of the nasopharyngeal airway might help. Any patients with craniofacial abnormality should be considered for surgical mandibular advancement, with or without maxillary advancement. These are highly skilled procedures that must be carried out in specialist centres.

**Fig. 47.5** Mechanism of action of continuous positive airway pressure. Left-hand panel shows mechanism of airway obstruction with the throat being sucked closed by the negative intraluminal pressure. Right-hand panel shows the throat being blown open by the continuous positive airway pressure applied by nasal mask.

## Continuous positive airway pressure

Those patients with severe symptoms and those not responding to the above measures require a trial of CPAP [92]. CPAP blows open the upper airway, thus preventing apnoeas, hypopnoeas, increases in upper airways resistance and snoring. CPAP is usually applied via an external nasal mask (Fig. 47.5), although some patients prefer intranasal devices. Therapy must be initiated with a careful explanation to each patient of the benefits and potential problems of CPAP. Educational videos are a useful adjunct to explanations by doctors and nurses. The patient must then be sized for an appropriate mask; each sleep centre should hold in stock at least 20 different sizes of masks from differing manufacturers so that an adequate fit can be achieved for each patient. Each patient should try CPAP for at least 30 min using the correct mask during the daytime to become accustomed to the sensation before returning for an overnight titration study. This sets the pressure required to keep the patient's airway patent and to minimize arousals: too high a pressure results in the patient being kept awake, while too low a pressure does not effect airway patency. 'Split night' studies, with the first part of the night for diagnosis and the second for CPAP titration, can be used in many patients with severe sleep apnoea but their role in milder disease is still unclear [93].

CPAP is one of the most satisfying therapies to deliver in that it can completely transform a patient's lifestyle. Patients who were unable to perform their job or drive safely because of sleepiness and who were subjected to considerable domestic strife can be returned to normality overnight, a situation rare in respiratory medicine. Randomized placebo-controlled studies have shown that CPAP improves symptoms, sleepiness, quality of life, mood, cognitive function, IQ and driving performance [90,91,94]. Uncontrolled data also suggest that CPAP may improve sleepiness [95], quality of life [96] and survival [48]. Recent evidence indicates that CPAP improves driving performance [97], decreases the rate and cost of

road traffic accidents [98], improves work efficiency and decreases time off work through ill-health [99].

Recently, the efficacy of CPAP has been challenged by Wright and colleagues [100]. At the time, these authors were correct in stating that there were few randomized controlled trials; however, many such studies have since been carried out and their results reviewed [101]. There is no real doubt that CPAP is effective in many patients, a conclusion shared by a recent systematic review [102], although there is a real need for further information on the cost-effectiveness and long-term use of CPAP.

Like all therapies, CPAP has side-effects. One of the major problems is the obtrusive nature of the device and careful education is the most important way of minimizing this problem. Despite careful mask fitting, local problems sometimes arise and mask sizes may need to be changed. The most common side-effects relate to nasal drying, rhinitis or dry mouth [99], all of which appear to be due to mouth leaks. Mouth leaks increase the flow of air through the nasopharynx, which may not only produce nasal drying and rhinitis but also increase airflow resistance, thus decreasing the effect of pressure delivered to the nasopharynx. Management should involve trying a chin strap but if this is not successful, then a heated humidifier may be necessary. Other problems include abnormal bloating that may be difficult to manage, although pressure reduction may prove satisfactory.

As with any other form of chronic therapy, including treatment for asthma [103], patient compliance with therapy is not as high as might be hoped. On average, patients on chronic CPAP use their machines for around 4–5 h per night but there is wide variation between subjects. Short-term trials yield slightly lower compliance figures [104], probably because those who use their machines early only rarely abandon the therapy subsequently. It is not yet clear whether symptoms or initial sleep study findings can be used to predict the subsequent use of CPAP by patients, the author's own data indicating no useful relationships [104].

Follow-up of patients on CPAP must include checking for side-effects, checking the function of the mask, tubing and machine, and monitoring objective use of therapy from the time clock built into the machine, since patients are frequently inaccurate in their estimate of use [104]. Annual electrical safety checks are standard for CPAP machines.

Bilevel ventilation via a nasal mask is an acceptable form of treatment for many patients with SAHS. However, it is significantly more expensive than CPAP and there is as yet no evidence that patient compliance or outcome is improved by using this method as opposed to CPAP [105].

Those patients who do not tolerate CPAP and in whom weight reduction is either not appropriate or unachievable should be considered for either dental devices or surgery.

## Oral devices

The role of dental devices in the treatment of sleep apnoea is unclear. These devices, which the subjects only use overnight, often advance the mandible and may decrease snoring and potentially also the frequency of apnoeas plus hypopnoeas [106]. Recent evidence from controlled trials suggests that oral devices may be effective in some patients with SAHS [107,108]. These data indicate that patients like oral devices and that these devices improve, but do not usually normalize, nocturnal breathing. Further studies investigating outcome measures and compliance with oral devices are awaited with interest before their role in the therapy of sleep apnoea can be stated with certainty. At present they have a role in patients who decline or do not comply with CPAP therapy, but whether they are as effective as CPAP as primary therapy remains to be seen.

## Otorhinolaryngological surgery

There is considerable controversy over the role of uvulopalatopharyngoplasty, whether carried out by conventional surgical techniques or by laser. Unfortunately, there are no objective data from controlled clinical trials that indicate high success rates [109,110]. In addition, the operation tends to be painful for around 2 weeks and has been associated with significant morbidity and very occasional mortality [111,112]. Casual readers of the literature should be careful not to be confused by differing definitions of success rates between studies, few of which use definitions of cure that involve returning the frequency of apnoeas/hypopnoeas and symptoms to normal levels. Furthermore, those patients who fail to benefit from uvulopalatopharyngoplasty and who then need CPAP have difficulty with pressure leaking out through the mouth, and have more side-effects and lower use of CPAP [113].

The theoretical problem with uvulopalatopharyngoplasty is that it addresses airway occlusion only at the palatal level, whereas obstruction generally takes place at both the retropalatal and retroglossal levels [15,16]. The earlier hope that localization of the prime site of obstruction as the retropalatal level would improve the success rate of uvulopalatopharyngoplasty has not been borne out [114,115]. There is dispute whether uvulopalatopharyngoplasty improves survival in patients with SAHS [48,116]. In selected centres, this operation has been augmented by partial glossectomy and significant success rates have been claimed to ensue.

## Faciomaxillary surgery

In a few centres around the world, mandibular plus maxillary advancement has been shown to benefit some

patients [117]. At present, patients who may benefit from this approach should be treated by surgeons who have experience in this area. Patients who should be considered for such procedures are those with abnormal cephalometric findings and narrowed upper airway. Further factors in favour of this approach include relatively younger patients, thinner patients and those not able to tolerate CPAP.

### Upper airway pacing

Pacing of the upper airway opening muscles by external or internal electrodes has been suggested as a possible treatment for SAHS [118]. Thus far, there is insufficient evidence available to recommend this approach.

### Tracheostomy

This option must be remembered as a possibility in severely ill patients intolerant of CPAP, although it is rarely needed.

### Central sleep apnoea

There is a small minority of patients who have true central apnoeas that do not respond to CPAP. Such patients generally have coexisting cardiovascular or cerebrovascular disease. When symptoms are troublesome, the best treatment in such cases is usually nocturnal intermittent positive-pressure ventilation via a nasal mask [41]. Aceta-

zolamide therapy has been shown to help some patients [119].

### Training

It is obviously essential that those dealing with any area of medicine are adequately trained in the clinical, diagnostic and treatment approaches relevant to that subspecialty. This is a particular problem in newly evolving areas of medicine such as the management of sleep disorders. Throughout the world, guidelines are being drawn up indicating the training requirements. The British guidelines, published by the Royal College of Physicians of London [120], indicates that trainees in respiratory medicine who wish to direct a sleep laboratory or to make sleep disorders a major component of their work should receive at least 12 months of specialist training in this area. In addition, it is recommended that all respiratory physicians in training should receive the equivalent of at least 3 months' education in a sleep laboratory during their training programme. These guidelines have yet to be rigorously enacted.

### Conclusions

Our understanding of SAHS is rapidly increasing. This is a clinically rewarding area that all respiratory physicians should understand so that they may identify potential patients and refer them for appropriate investigation and treatment.

# HYPERVENTILATION SYNDROMES

ANTHONY SEATON

The symptom of breathlessness is one of the principal reasons for referral of a patient to a chest clinic and for acute admission into hospital. It is a symptom that everyone is familiar with from the effects of exertion but one that not uncommonly causes difficulties for individuals in distinguishing normal from abnormal breathlessness. The previously fit person who becomes unfit and fat from lack of exercise and overeating notices shortness of breath during activities that earlier had been carried out without difficulty, and may interpret this as indicating serious heart or lung disease. Similarly, anxious or obsessive people may seize upon an awareness of the process of respiration and interpret the pattern as abnormal. Once focused on such a symptom, it is easy to develop an obsessive interest in the suspected abnormal function of the organ, sufficient to prompt a visit to a doctor. Any subsequent indication by the doctor of uncertainty about the cause or implications of the syndrome is likely to reinforce the patient's anxiety and help perpetuate the complaint. It is therefore important that all chest physicians, to whom such patients are often referred, are aware of the syndrome of behavioural breathlessness, its causes and the methods of managing it.

The two important syndromes of behavioural breathlessness are hyperventilation, which usually occurs in attacks but rarely may become chronic, and sighing. Both types are described by patients as shortness of breath and need to be distinguished from breathlessness of organic aetiology. Hyperventilation in normal people causes a wide range of symptoms related to hypocapnia and alkalosis, vasoconstriction and stimulation of chest wall muscle receptors, and these symptoms may be interpreted by patients with hyperventilation syndrome as further evidence of organic disease.

## Control of respiration

This is discussed in Chapter 2. The involuntary system is based on rhythmical discharge of neurones in the pontine and medullary respiratory nuclei that respond to stimuli

from the carotid and medullary chemoreceptors; the receptors in the carotid bodies respond primarily to arterial hypoxia while those in the floor of the fourth ventricle respond to arterial and cerebrospinal fluid pH and  $P_{CO_2}$ . In addition, sensory stimuli from lung and airway receptors transmitted via the vagus nerve may modify the pattern of respiration. Inspiratory and expiratory neurones are found in the spinal cord, supplying the diaphragm via the phrenic nerve (C3–C5) and the intercostal, accessory respiratory and abdominal muscles through spinal nerves down to T12.

Voluntary control of respiration is possible because higher neural centres are able temporarily to override the brainstem control centres, by direct inhibition or stimulation of spinal motor nerves via corticospinal pathways or of brainstem control via corticobulbar pathways. It is with this voluntary control of respiration that this chapter is primarily concerned.

## Causes

Hyperventilation may be defined as ventilation sufficient to reduce  $P_{aCO_2}$  while maintaining a high  $P_{aO_2}$ . This excludes breathlessness due to diseases that impair gas exchange, such as pulmonary fibroses and cardiac failure, and those with airflow obstruction such as asthma. However, it should be noted that behavioural hyperventilation can occur in these conditions as readily as it can in an otherwise healthy person. The definition also excludes breathlessness due to exercise and to hypoxia. There are organic causes of hyperventilation as well as psychogenic, and the most important are shown in Table 48.1. In any case of suspected hyperventilation it is essential to reassure oneself that there is not an organic cause. This differential diagnosis is discussed below.

## Symptoms

Haldane and Poulton [1] first described the characteristic and varied symptoms associated with hyperventilation

**Table 48.1** Causes of hyperventilation.

---

<i>Lung disease</i>
Asthma
Pulmonary embolism
Multiple arteriovenous fistulae
<i>Brain disease</i>
Midbrain tumour
Meningitis
Meningeal lymphoma
Langerhans' histiocytosis
Rett's syndrome
<i>Metabolic acidosis</i>
Renal failure
Renal tubular acidosis
Diabetic ketoacidosis
Lactic acidosis in shock
Gastrointestinal loss of bicarbonate
Metformin acidosis
Aspirin poisoning
Methyl alcohol poisoning
Ethylene glycol poisoning
<i>Psychogenic</i>
Panic attacks
Anxiety, depression
Hysteria

---

and hypocapnia, and generations of medical students have since experienced a selection of these symptoms in their physiology practical classes. The most common are lightheadedness, dizziness and paraesthesiae, which may lead to syncope and tetany. Other symptoms include chest pain, palpitations and a range of feelings of psychological discomfort. Symptoms occur at around an end-tidal  $P_{CO_2}$  of 2.66 kPa (20 mmHg) on average, with a threshold of no higher than 3.86 kPa (29 mmHg) [2]. Various mechanisms probably contribute to their causation, including alkalosis, cerebral and peripheral vasoconstriction, stimulation of chest wall stretch receptors and falls in blood phosphate concentrations [3–7]. The subject has been well reviewed by Gardner [8].

## Behavioural breathlessness

### Hyperventilation

#### Clinical features

Patients with psychogenic hyperventilation complain of breathlessness disproportionate to the amount of exercise taken or any cardiopulmonary impairment detected [8–10]. Indeed, they frequently complain of episodic breathlessness at rest. Their symptoms often vary substantially from day to day and, if asked, admit that breathing in is harder than breathing out. Breathlessness may be,

though not always, associated with other symptoms. These may mimic cardiac disease with chest pain or palpitations, and in some patients hyperventilation may provoke coronary artery spasm and genuine attacks of angina [11,12]. Neurological disease may be mimicked, with dizziness, lightheadedness, syncope, tingling in the fingers and muscle cramps. Panic attacks may be a feature [13,14], and the author has seen one patient with an epileptic tendency in whom grand mal attacks were brought on by hyperventilation. The term 'hyperventilation syndrome' was introduced in 1937 to describe this condition, in the belief that the symptoms were the result of the hyperventilation [15].

Investigation of such patients has shown that a high proportion suffer from symptoms indicating a psychiatric illness [9]. Depression, not always clinically overt, is common as is anxiety. In a relatively few cases, hysteria or motivation by the prospect of gain, for example sympathy from a spouse or in pursuit of litigation, may be important factors. A careful history often indicates that the patient has an obsessional personality and that the perceived illness was provoked by a traumatic event such as bereavement, separation or divorce. Hyperventilation does not seem to be a feature of the chronic fatigue syndrome [16], although it might be expected to occur in some cases. Bad medical management has a way of making matters much worse, and resentment at either actual or perceived medical incompetence may be detected in patients with hyperventilation. Doctors involved in examining lawyers' clients as part of civil litigation proceedings frequently see patients with disproportionate breathlessness. Not all in this situation are deliberately exaggerating (though many are); some have been made genuinely anxious by a perceived gloomy prognosis, given by rather thoughtless or stupid doctors, relating to a trivial condition such as pleural plaques or mild asthma and have developed psychogenic breathlessness.

### Diagnosis

An essential step in making the diagnosis is to exclude an organic cause of the breathlessness. The syndrome is usually suspected strongly by the experienced chest physician from the history and from observation of the patient while taking it. A careful examination of lungs and heart is not only essential for diagnosis but is also of therapeutic value. It should be remembered that hyperventilation may occur in patients with organic lung or heart disease and is not uncommon in patients with asthma and other chronic airways disease [17,18]. In such subjects, a peak flow chart is of considerable value in allowing the dissociation between symptoms and flow rates to be demonstrated. Detailed lung function testing and ECG are similarly useful to reassure the patient about the absence of organic disease.

A simple exercise test, such as an 8-min run or brisk walk in or near the clinic, may be helpful as a means of indicating to the patient that exercise tolerance is unimpaired. However, many such patients complain of severe symptoms during exercise and formal testing has shown that inappropriate hyperventilation may occur on exercise as well as at rest [9].

Some physicians who have studied the syndrome find hyperventilation tests of value in diagnosis, by reproducing the patient's symptoms. Howell [9] recommended a simple test in which the patient is asked to take 20 deep breaths and to stop if he or she feels odd in any way. If this does not reproduce the patient's symptoms, the diagnosis of psychogenic breathlessness is unlikely to be correct, whereas if it does the diagnosis finds support. There is little to be gained clinically from more complex tests monitoring end-alveolar  $P_{CO_2}$ . There is no clear relationship between the rate of change in  $P_{CO_2}$  and symptoms [2], and it has been shown in a controlled study that patients with hyperventilation syndrome develop symptoms similarly with hypocapnic and isocapnic hyperventilation [19]. This study also demonstrated, by using ambulatory  $P_{CO_2}$  monitoring, that symptoms did not correlate with changes in  $P_{CO_2}$ . It seems therefore that hyperventilation producing hypocapnia is but one symptom of the underlying psychological illness, and not necessarily the cause of the other somatic symptoms. In support of this concept, other studies have shown symptoms to be provoked by psychological stress tests as readily as by hyperventilation [20].

### Differential diagnosis

The main problem of differential diagnosis arises in patients with genuine organic disease such as asthma or other chronic heart and lung disease [21]. In lung disease, demonstration of inappropriate breathlessness on formal exercise testing or on a chart recording both symptoms and peak flow rate is necessary. In the case of chest pain, reproduction by deep breathing in the absence of ECG changes is reassuring. If ischaemic changes do occur, further investigation by angiography and hyperventilation is obviously necessary. Two respiratory diseases in particular may cause hyperventilation with no other obvious chest signs: pulmonary embolism and multiple arteriovenous fistulae [22–24]. In breathlessness due to pulmonary embolism, anxiety is often quite justifiably present and it is not uncommon for the diagnosis of psychogenic hyperventilation to be considered.  $P_{aCO_2}$  is low but  $P_{aO_2}$  is also usually reduced and the alveolar–arterial oxygen gradient is increased. Arteriovenous malformations may be multiple and not obvious on chest radiography, although finger clubbing and often a sufficiently low  $P_{aO_2}$  to cause cyanosis are present.

Hyperventilation due to acidosis may still catch the unwary [25], but in contrast to psychogenic breathlessness

the patient with Kussmaul respiration may look remarkably unconcerned about what appears to be distressing breathlessness. Measurement of arterial blood gases together with blood sugar and urea quickly show the cause of the problem. The acidotic respiration of aspirin or methyl alcohol poisoning constitutes a well-known presentation in the emergency department, since these patients often look suitably anxious or depressed. Diagnostic confusion should not arise in the intensive care unit with breathlessness due to sepsis or blood loss [26]. Neurological disease is a relatively rare cause of hyperventilation, and may cause considerable diagnostic difficulties if it is not considered. A stroke in the region of the brainstem, multiple sclerosis, malignant meningeal infiltration by lymphoma, and Langerhans' cell histiocytosis (histiocytosis X) have all been described as rare causes [27–31]. In these syndromes, the hyperventilation is chronic.

Rett's syndrome is a brain disorder of young females, starting in infancy and progressing through the first two decades of life, characterized by autistic behaviour, abnormal hand movements, epilepsy, dementia, neurogenic scoliosis, and episodic hyperventilation and apnoea [32–34]. It is perhaps caused by a deficiency of dopaminergic neurotransmitters. The disordered control of breathing appears to result from higher cortical brain damage, since polysomnographic studies in such patients have shown a normal pattern during sleep [35].

### Management

The first step in the management of psychogenic hyperventilation is exclusion of organic disease and reassurance of the patient that none is present. In many cases this is possible at the time of the first consultation if a few simple tests as described above prove to support the diagnosis. This reassurance should be firm, as any doubt in the doctor's mind will be readily apparent to the anxious patient. An acute attack in an anxious individual is very easily recognized, and once seen is not forgotten; it is usually managed by asking the patient to rebreathe in a paper bag, thus allowing the symptoms generated by hypocapnia to be relieved and their cause demonstrated. Subsequent steps in management are still at the stage of individual preference based on experience, experience quite likely to be of application only to the sorts of patients that one physician sees. However, in general a sensible approach would seem to be as follows.

#### *Explain the breathlessness*

Having been told that there is nothing the matter with heart and lungs, the patient, though reassured, still wishes to have an explanation of the symptoms. It is necessary therefore to explain how breathing normally occurs involuntarily but that awareness of the process can cause alter-

ations in its pattern. A useful analogy is running downstairs, something that most people can do in a hurry but that can become awkward and even lead to a fall if too much thought is given to where one's feet should be placed on every step. It can then be explained that once one becomes aware of the process of breathing it is a small step to becoming anxious that it is not proceeding normally and this may lead to a vicious cycle of increasing anxiety and breathlessness. This explanation needs to be approached with care as some patients are quite resistant to the suggestion that their symptoms are non-organic and may interpret such an idea with denial or outright hostility. Clearly, the rapport established with the patient in the consultation is a determinant of success in managing this part of the process. The author prefers to discuss these mechanisms in a way that emphasizes their organic aspects—control by the brain, symptoms of hypocapnia (despite what was said above about this not necessarily being the cause of all the symptoms) and so on—and to explain that the syndrome is a common accompaniment of stress of one sort or another. The concept of 'stress' is now quite well appreciated by the general public and does not seem to be associated with the same amount of perceived stigma as a more psychiatric label such as depression. It is useful to point out that the syndrome is common and one with which chest physicians are quite familiar and which occurs particularly in perfectionists.

#### *Evaluate the effectiveness of reassurance and explanation*

In many less severe cases, this simple procedure is enough to give the patient sufficient insight into the condition to relieve anxiety and cure the symptoms. It is therefore sensible not to take the process any further initially but to arrange to review the patient after an interval in order to assess progress. It is apparent that overall cure depends on relief of the primary cause, and it may well be that the hyperventilation disappears but that other psychosomatic symptoms replace it. If this is the case, the psychological problem needs to be addressed, not necessarily by the chest physician.

#### *Discuss with the patient possible causative factors*

Again this requires a delicate approach and is often best done in terms of stress. The history may have revealed evidence of symptoms of depression or anxiety and of an obsessional or hysterical personality. Possible precipitating factors should be explored by asking tactfully about

any events that may have occurred about the time that the symptoms started. Apart from obvious factors such as marital difficulties and bereavement, common causes nowadays include stress in the workplace, loss of employment, troublesome children and financial worries.

#### *Treat the cause*

If there is an important environmental cause, such as domestic or work-related problems, these can be addressed by appropriate agencies and this should certainly be considered before starting drug treatment. In severe cases, treatment of the symptom of hyperventilation alone is unlikely to be of benefit without additional psychological treatment. However, various forms of re-education of breathing patterns have been reported to be successful in relieving the symptom [36,37].

#### *Take a positive attitude towards recovery*

It is the author's practice, based on experience, to be optimistic about recovery. If the patient proves able to complete a simple exercise test it is often possible to demonstrate that no harm has come from that exercise and to persuade the individual to initiate a personal exercise training programme that allows confidence to increase that no serious disease is present. Since many of these patients are slightly, or indeed very, obsessional, they may take well to such advice. One of the author's patients responded to the suggestion to go swimming regularly by doing so daily in the sea off Aberdeen throughout a Scottish winter. Fortunately she did not succumb to pneumonia before being advised that the local pool was perfectly adequate.

#### **Sighing breathlessness**

Sighing breathlessness is a minor variant of the hyperventilation syndrome but one seen quite commonly in outpatient clinics [38,39]. The patient complains of the need to take a deep breath or of being unable to get a really good breath. Sometimes sighing can be observed during the consultation, occasionally to the point that one has to stifle a feeling of annoyance that one's best efforts are so boring! The symptom is usually a manifestation of mild anxiety, and reassurance that there is no abnormality of lung function (after appropriate spirometry) is all that is needed. A simple exercise test is of particular value in demonstrating to these patients that all is well with their lungs.

# DISEASES OF THE MEDIASTINUM

DOUGLAS SEATON

## Anatomy of the mediastinum

The mediastinum comprises those structures situated between the lungs at the centre of the thorax, the word being derived from the Latin *medius* meaning middle and *stare* to stand. It is bounded superiorly by the thoracic inlet, inferiorly by the diaphragm, posteriorly by the thoracic spine, anteriorly by the sternum and laterally by the parietal pleurae. For descriptive purposes anatomists have drawn an imaginary line on the mediastinal map from the fourth dorsal intervertebral disc (the point at which the paravertebral fascia attaches) to the sternal angle of Louis, thereby creating the superior mediastinum. The remaining inferior compartment is subdivided vertically by the heart to give anterior, middle and posterior mediastinal compartments (Fig. 49.1).

A knowledge of the normal contents of the four mediastinal compartments is helpful when considering the possible causes of a radiographic abnormality in the mediastinum or the likely consequences of its enlargement. All compartments contain vessels, lymph nodes, nerves, fat and connective tissue.

1 The superior mediastinum contains the aortic arch, its three large branches, the upper half of the superior vena cava and its two innominate tributaries. It is also traversed by the trachea, the oesophagus, the thoracic duct and the phrenic, vagus, cardiac and left recurrent laryngeal nerves.

2 The anterior mediastinum contains the thymus gland, which also extends into the superior compartment.

3 The posterior mediastinum contains the spinal nerve roots, which lie in the paravertebral gutters, the descending aorta, the oesophagus, the azygos and hemiazygos veins, the thoracic duct, the vagi and the splanchnic nerves.

4 The middle mediastinum contains the heart and pericardium, the ascending aorta, the lower half of the superior vena cava, part of the azygos vein, the pulmonary arteries and veins, the tracheal bifurcation, the phrenic nerves and inferior vena cava.

## Mediastinal tumours and cysts

Predictably, the reported series of mediastinal masses appear in the surgical literature and generally include those tumours and cysts requiring an invasive procedure for diagnosis. For detailed descriptive purposes, many lesions are conventionally omitted from such series although they remain important in the differential diagnosis of a mediastinal lesion. These include the following:

- 1 diaphragmatic lesions, including eventrations and herniae (commonly oesophageal hiatus, occasionally foramina of Morgagni, Bochdalek or post-traumatic), as discussed in Chapter 46;
- 2 oesophageal tumours and megaesophagus due to achalasia of the cardia;
- 3 mediastinal metastases and direct invasion of the mediastinum by tumour from other anatomical areas;
- 4 mediastinal lymph node enlargement as a manifestation of systemic disease, including lymphoma (see Chapter 42) and non-neoplastic granulomatous disease;
- 5 retrosternal extension of a thyroid goitre in the neck, except for a minority that cannot be removed by a cervical approach;
- 6 aneurysms of the aorta and its major branches;
- 7 ventricular aneurysms;
- 8 a minority of rare conditions, including tumours of the trachea and heart, skeletal lesions and paravertebral abscess.

## Incidence

The overall incidence of mediastinal cysts and tumours is not known. A series of 105 patients collected over a 10-year period in Edinburgh resulted in an estimated incidence of 1 per 100 000 per year. These lesions were seen approximately three times more commonly than bronchial adenomas over the same period. Conversely, for every case of primary mediastinal cyst or tumour, 30 cases of bronchial carcinoma and seven cases of oesophageal carcinoma were seen [1]. North American estimates for

Fig. 49.1 Subdivisions of the mediastinum.

mediastinal lesions have ranged from 1 per 2500 to 1 per 3400 admissions to large medical centres [2,3].

The relative proportion of different mediastinal lesions varies according to individual series and must reflect both local patterns of referral and surgical practice. Four large series containing 974, 251, 209 and 202 cases all found that neural tumours were the most common mediastinal lesion, accounting for 20–27% of cases [4–7]. The two largest series placed thymic lesions a close second (19 and 26% respectively), with developmental cysts a close third (18 and 21% respectively) [4,5]. Thus for practical purposes, neural tumours, thymic lesions and developmental cysts can each be regarded as having a similar incidence of about 20%.

If the foregoing three groups of tumours vie for first place, then mediastinal teratomas and lymphomas compete for fourth. One series did not include cases of extrathymic mediastinal lymphoma (regarded as a mediastinal manifestation of a systemic disease) [5], but those that included this pathological group found that it accounted for approximately 12% of cases compared with about 11% for teratomas and other germ-cell tumours [4–7].

Neural tumours, thymic lesions, developmental cysts, teratomas/germ-cell tumours and lymphoma together account for approximately 88% of primary mediastinal masses, those lesions that remain being rare (Table 49.1). These frequencies are in broad agreement with the earlier calculations of Silverman and Sabiston [8].

The relative frequencies of primary mediastinal lesions differ in children in that neural tumours are more common, accounting for 40% of the total compared with

20% in adults. Conversely, thymic cysts and tumours, which make up 20% of adult lesions, are extremely rare in childhood. Most series place lymphoma as the second most common mediastinal lesion in children (20%), with teratomas and developmental cysts accounting for about 10–15%.

### Clinical features

About one-third to half of patients in whom mediastinal cysts or tumours are found are asymptomatic at the time of diagnosis [2,5,8–10]. These figures also apply to children [8,11]. If the practice of performing routine chest radiographs on apparently healthy subjects were to become more widespread, then this proportion would increase. This is illustrated by one series in which 72% of military personnel found to have mediastinal tumours on routine radiographic screening were symptom-free [12].

The absence of symptoms at the time of diagnosis is a good prognostic sign as about 90% of these patients have a benign lesion [1,10,12], whereas in patients who are symptomatic about half have benign and half malignant lesions. It follows that although malignant lesions are more likely to produce symptoms than benign ones, the presence of symptoms need not imply malignancy.

The symptoms most frequently encountered are cough, breathlessness and chest pain [1,2,8–10,13]. These are usually a consequence of compression or invasion of mediastinal structures. Malaise, anorexia, weight loss, weakness and fever may occur as the non-specific features of any malignant process. When cough is present it is often recurrent and the patient may receive repeated courses of

antibiotic for supposed respiratory tract infection before referral to hospital. Haemoptysis may occur and sometimes the contents of a ruptured cyst are expectorated. Dyspnoea may be associated with wheeze and may lead to inappropriate treatment for asthma. Proximal airway compression is usually accompanied by stridor, which need not always imply a neoplastic cause [14]. Chest pain may be caused by either thoracic wall invasion or intercostal neuralgia and need not indicate inoperability.

Oesophageal compression results in dysphagia, while compression of the superior vena cava causes neck vein engorgement and facial swelling, a syndrome more often associated with malignancy than not. Mechanical traction

**Table 49.2** Some systemic and endocrine syndromes associated with mediastinal tumours (see text).

Syndrome	Tumour
Myasthenia gravis	Thymoma; thymic hyperplasia
Gynaecomastia, Klinefelter's syndrome	Non-seminomatous germ-cell tumour
Hyperparathyroidism	Parathyroid adenoma
von Recklinghausen's disease	Neurofibromas
Diarrhoea, sweating, tachycardia, headache, hypertension	Functioning autonomic nervous system tumours
Spinal cord compression	Neural (dumb-bell) tumours
Hypoglycaemia	Sarcomas, benign teratomas
Hypogammaglobulinaemia, hypoplastic bone marrow, connective tissue diseases, Whipple's disease	Thymoma
Haematological malignancies	Thymoma, non-seminomatous germ-cell tumours
Malaise, weight loss, pyrexia	Lymphomas, sarcomas, any malignant tumour
Cushing's syndrome	Thymic carcinoid tumour
Multiple endocrine neoplasia syndromes	Parathyroid adenomas

or compression produces neurological impairment less frequently, but may result in hoarseness due to left recurrent laryngeal nerve palsy, hemidiaphragmatic elevation due to phrenic nerve palsy, or incomplete ptosis and a constricted pupil due to involvement of the upper thoracic sympathetic nerves. Spinal cord compression may result from the dumb-bell type of neural tumour (see Fig. 49.3c, p. 1275). Anterior or middle mediastinal tumours may rarely result in pericarditis and cardiac tamponade or heart failure due to obstruction of the right ventricular outflow tract [10]. Pleural effusion is occasionally present and may be chylous because of involvement of the thoracic duct or as a consequence of lymphangiomias [15,16].

In infants and small children compression of the upper airways, superior vena cava and oesophagus may develop with great rapidity as a result of the rapid expansion of a foregut cyst or other lesion in the close confinement of the superior mediastinum. In adults a similar life-threatening situation may rarely arise from the sudden expansion of a retrosternal goitre as a result of haemorrhage into its substance.

Apart from symptoms and signs arising as a result of the compression or invasion of adjacent mediastinal structures, there are several systemic or endocrine syndromes associated with mediastinal tumours. These are listed in Table 49.2 and discussed individually under the appropriate

ate pathological headings that follow. All of them are rare, with the exception of myasthenia gravis occurring in association with thymic lesions.

### Mediastinal neural tumours

Mediastinal neural tumours (Table 49.3) are usually but not exclusively found in the posterior mediastinum in both adults and children and comprise the largest single group of tumours in this compartment. They account for about 20% of mediastinal lesions in adults [17]. Over three-quarters of neural tumours in adults are benign, whereas about half are malignant in children [18]. The terminology surrounding these tumours may confuse as the literature is stiff with synonyms. The embryogenesis of the cell types from which neural tumours are derived is a controversial field. However, it has been claimed that during the folding of the primitive dorsal neural plate, certain ectodermal cells separate from it and migrate so that they come to lie apart from the developing neural tube in the embryo. These have been called neural crest cells and it is supposed that they subsequently differentiate via primitive blast cells into different types of mature neural cell, including peripheral nerve cells (or neurocytes) and peripheral nerve sheath (or Schwann) cells.

Peripheral nerve cells (neurocytes) are those from which sympathetic ganglia, including the spinal sympathetic ganglia, are formed. It is from these cells or from more primitive neuroblasts that mediastinal nerve cell, neurocytic or autonomic tumours develop. Benign mediastinal

neurocytic tumours arising from the sympathetic ganglia in the thorax are called ganglioneuromas. The malignant counterparts of these tumours are ganglioneuroblastomas, in which histological ganglionic differentiation remains strong, and the more aggressive neuroblastomas, which are in fact undifferentiated ganglioneuroblastomas in which ganglion cells are no longer an easily recognizable feature. Some earlier authors referred to neuroblastomas as sympatheticoblastomas [19], while others regarded this as a histological subtype [10]. All tumours belonging to this group may produce catecholamines and they are more common in children.

Mediastinal paragangliomas are very rare neurogenic tumours that arise, as the name implies, from the paraganglia, the cellular precursors of which are likely to have migrated from the embryonic neural crest to their final destination juxtaposed to the ganglia of the autonomic nervous system. They are found in the posterior mediastinum in the costovertebral sulcus and also in the region of the aortic arch. These tumours, which tend to occur in adults, may also be hormonally active, producing catecholamines. Hormonally inactive paragangliomas of the chemoreceptor system have been called chemodectomas, while those near the aortic arch have been called aortic body tumours. Hormonally active mediastinal paragangliomas have previously been classified as phaeochromocytomas because they may be morphologically indistinguishable from the adrenal paraganglioma of that name. Indeed all these mediastinal tumours are paragangliomas, so it is best to drop the terms 'chemodectoma' and 'aortic body tumour' and reserve the term 'phaeochromocytoma' for paragangliomas occurring in the adrenal medulla. The anatomical site of mediastinal paragangliomas can be described as aorticopulmonary for those found in the region of the aortic arch and aortic sympathetic for those found in the costovertebral sulcus of the posterior mediastinum [20]. It used to be thought that the presence or absence of chromaffin substance in paragangliomas correlated closely with hormonal activity, those that were chromaffin-positive being active (e.g. phaeochromocytoma) and those that were chromaffin-negative being inactive. However, it is now appreciated that the chromaffin reaction may be capricious [20] and that some chromaffin-negative paragangliomas may be hormonally active [21] and vice versa [22,23]; thus paragangliomas should be described as 'hormonally active/functioning' or 'hormonally inactive/non-functioning', without attaching complete reliance to their chromaffin status.

Nerve sheath cells give rise to both the Schwann cells and the perineural and endoneural fibrous tissue. Schwannomas (syn. neurilemmoma) are tumours that arise from Schwann cells, previously known as lemmocytes. It was thought that neurofibromas arose from perineural or endoneural fibrous tissue but it now appears

**Table 49.3** Mediastinal neural tumours (see text).

Currently favoured term	Synonyms

\* Benign neoplasm.

that they too arise predominantly from Schwann cells, although they contain all elements of the nerve. The fact that both these neoplasms may occur in the same patient and sometimes even within the same tumour mass lends further credence to a common cell of origin. Both schwannomas and neurofibromas were referred to collectively in the older literature as neurofibromas. They may be regarded as benign although neurofibromas and rarely schwannomas have potential for undergoing change to their malignant counterpart, the malignant peripheral nerve sheath tumour (MPNST). Earlier authorities used the terms 'malignant neurilemmoma' or 'malignant schwannoma' synonymously with MPNST [24]. A third and extremely rare type of nerve sheath tumour thought to be derived from either Schwann cells or their precursors is the granular cell tumour, originally thought to be of muscle cell origin and called granular cell myoblastoma [25,26].

### Peripheral nerve sheath tumours

There are three major neoplasms in this category, the benign schwannoma and neurofibroma and MPNST.

#### Benign: schwannoma and neurofibroma

##### *Relative frequency and pathological features*

In adult series, benign nerve sheath tumours constitute the largest single group of neural neoplasms in the mediastinum [4,5], although in children they are much less common than autonomic nervous system (syn. nerve cell or neurocytic) tumours [11]. Several authors have reported that neurofibroma is the more common tumour [2,5,13,27–29]. However, the majority of workers find that schwannoma is by far the most common and review of 10 different series reporting 398 cases of these two tumour types finds that 70% of them were schwannomas [2,4,6,9,13,27,28,30–32]. Histologically mixed forms have been reported in which the pattern varies between sections in the same tumour [28] and this may account for some differences in histopathological reporting. Most neural tissue in the mediastinum is situated posteriorly in the paravertebral gutters and for this reason benign nerve sheath tumours in common with other neurogenic tumours are often found in this location, although they may also arise from other intrathoracic nerves.

Schwannomas are rounded tumours that are well encapsulated and easily removed surgically [28]. They arise from the lateral aspect of their parent nerve, which is usually spinal although occasionally the sympathetic chain or rarely the vagus, phrenic or recurrent laryngeal nerves may be involved [32–34]. They have an organized architecture that may assume a pallisaded or reticular pattern of growth, referred to as Antoni types A and B respectively

[8,35]. Neurofibromas are also nearly always rounded with a similar gross appearance and although usually unencapsulated are generally easily removed [28]. They tend to expand from within the parent nerve, which is usually spinal [31], and present a different histological picture of a less orderly arrangement of tangled and reticular fibrous tissue in which all elements of the nerve trunk may be represented [9]. Both benign nerve sheath tumours enlarge slowly [32,36]; during this process cellular degenerative changes may occur in schwannomas but not neurofibromas [6]. Neurofibromas may be multiple and rarely take on a plexiform configuration in which the tumour assumes a serpentine shape, insinuating itself around the various mediastinal structures so that complete excision may be impossible [5,28,36]. In such cases, the patient is likely to have von Recklinghausen's disease (neurofibromatosis) type 1, and plexiform neurofibromatous proliferation in a limb or elsewhere may produce massive enlargement (elephantiasis neuromatosa). The reported frequency of type 1 (or peripheral) von Recklinghausen's disease in patients from whom neurofibromas are resected varies widely between series but approaches 30% on average [4,6,28,30,31]. Patients with this type of neurofibromatosis, which is inherited as an autosomal dominant, may have neurofibromas at every conceivable site, usually presenting with cutaneous lumps and multiple *café-au-lait* spots plus the common finding of a thoracolumbar scoliosis. Such patients may also have some schwannomas.

##### *Clinical features*

Schwannoma and neurofibroma are approximately equally distributed between the sexes. They may both occur at any age but are usually diagnosed between the ages of 30 and 60 years [4,32,36]. The majority are asymptomatic and are discovered following a routine chest radiograph (Fig. 49.2). When symptoms do occur they fall into the general pattern produced by any benign lesion that occupies space in the mediastinum (see above). Spinal cord compression as a result of a dumb-bell or hourglass tumour straddling the intervertebral foramen is a rare but well-recognized complication of both schwannomas and neurofibromas. Segmental pain may be caused by spinal nerve involvement. The radiographic appearances are of a solitary, sharply defined, rounded mass, usually occupying a paravertebral sulcus (Fig. 49.3a,b). The ribs may sometimes be splayed by lesions of sufficient size and the adjacent intervertebral foramen may be enlarged, particularly in the case of a dumb-bell tumour, the presence of which may be confirmed by spinal magnetic resonance imaging (MRI) (Fig. 49.3c). Posterior mediastinal opacities in patients with von Recklinghausen's disease are very occasionally caused by an intrathoracic meningocele, which may easily be mistaken for a neurofibroma on a chest radiograph. In this case the dura may herniate

through an intervertebral foramen, the meningeal sac coming to lie in the paravertebral gutter. Associated scalloping of the posterior margins of two or three adjacent vertebral bodies with splaying of the overlying ribs are characteristic findings, as is widening of the corresponding intervertebral foramen. The nature of this problem may be shown by MRI. If intervention is required, the sac may be excised and its neck closed at thoracotomy [37].

(a)

Both schwannomas and neurofibromas may very rarely occur intratracheally, in which case they may be treated by either endoscopic or laser resection [38,39]. Two cases of mediastinal schwannoma apparently occurring in association with nephrotic syndrome have been described in the literature [40]. Sudden, presumed dysrhythmic death has been reported in a young man with type 1 von Recklinghausen's disease, who was found at postmortem to have a massive neurofibroma involving the vagus nerve [33]. Uncomplicated benign neural tumours in the posterior mediastinum are conventionally removed by posterolateral thoracotomy, although more recently 'three-hole' thoracoscopic removal has been used. The latter procedure takes longer and may be difficult with large tumours but patients tend to have a shorter hospital stay and may return to work sooner [41]. Dumb-bell tumours are dealt with by a joint neurosurgical and thoracic approach (see below).

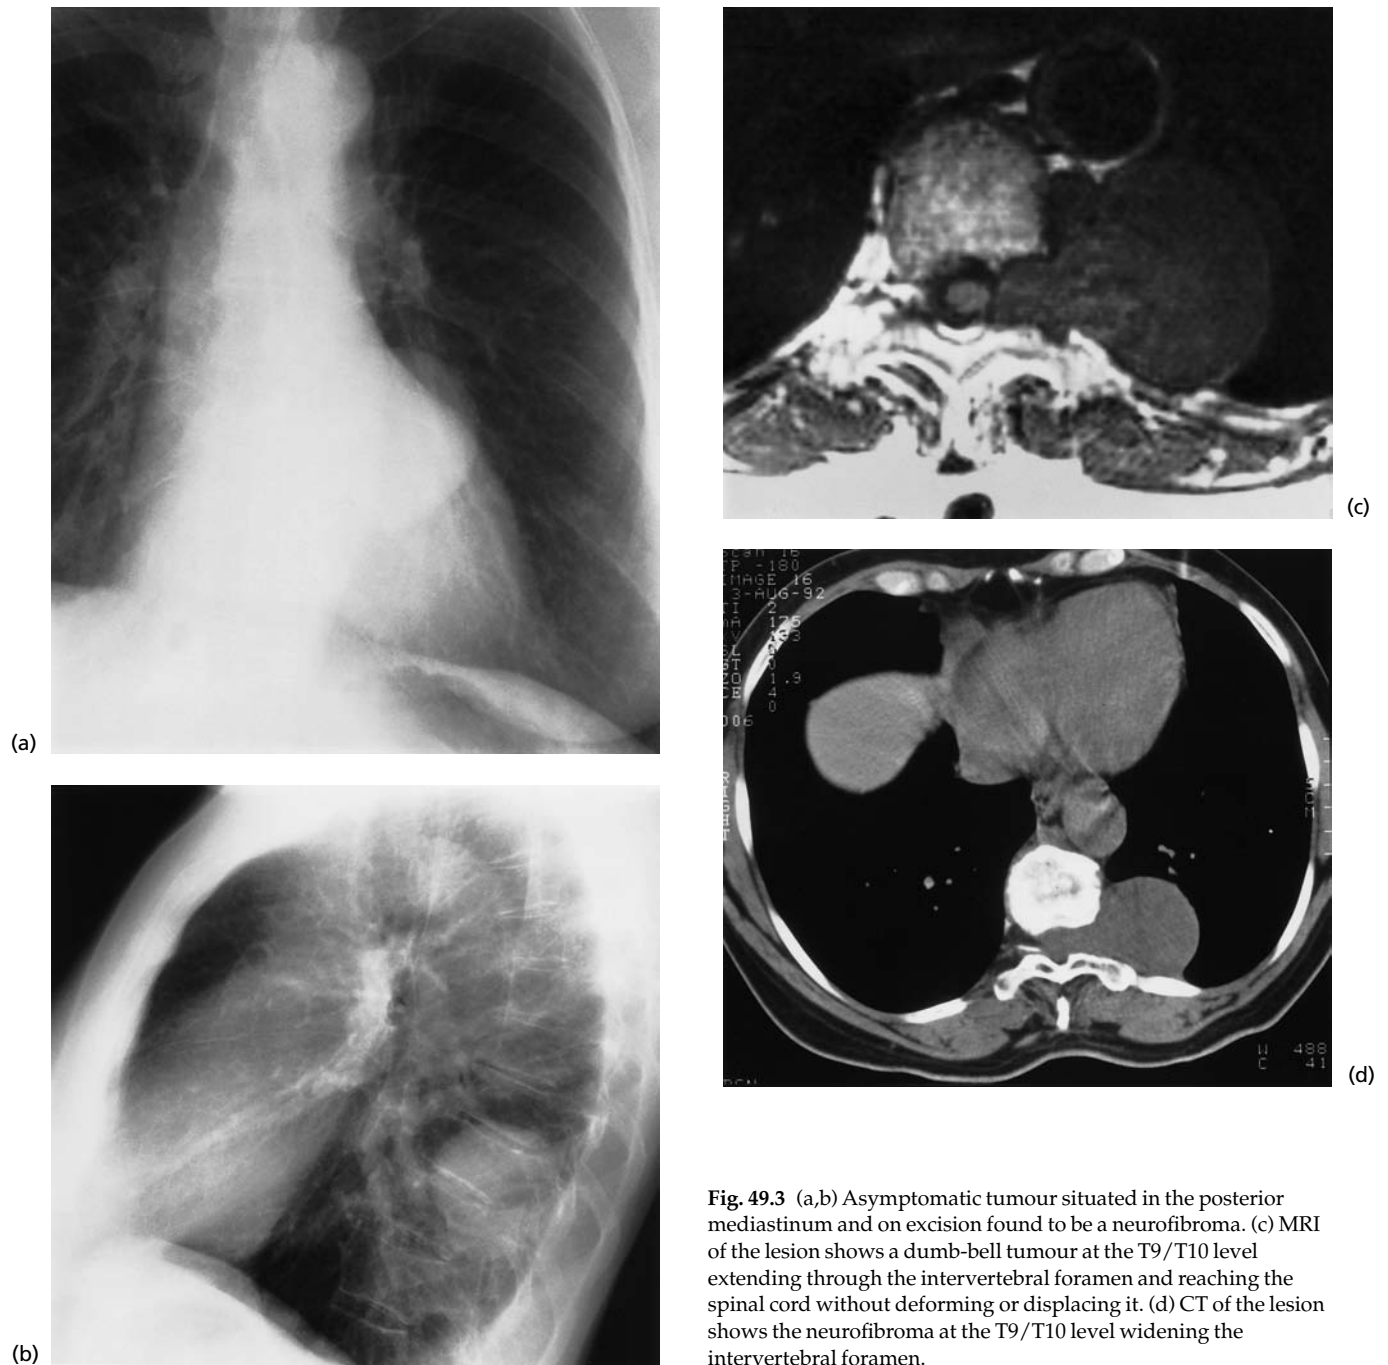

#### Malignant: MPNST

Although MPNST is now the usual term, there are the inevitable synonyms including neurosarcoma, neurofibrosarcoma, neurogenic sarcoma, malignant schwannoma and malignant neurinoma. About half of all cases are thought to occur *de novo*, the remainder developing in a neurofibroma or rarely in a schwannoma. They are more

(b)

**Fig. 49.2** (a) Asymptomatic right upper mediastinal tumour that on excision proved to be a neurofibroma. (b) MRI of the neurofibroma showing no evidence of spinal cord compression or displacement.

**Fig. 49.3** (a,b) Asymptomatic tumour situated in the posterior mediastinum and on excision found to be a neurofibroma. (c) MRI of the lesion shows a dumb-bell tumour at the T9/T10 level extending through the intervertebral foramen and reaching the spinal cord without deforming or displacing it. (d) CT of the lesion shows the neurofibroma at the T9/T10 level widening the intervertebral foramen.

likely to occur in patients with type 1 von Recklinghausen's disease and it has been estimated that 10–15% of these individuals harbour tumours that undergo malignant transformation. When this transformation occurs in this group of patients, the site is usually a large nerve trunk in the neck or an extremity, whereas mediastinal or superficial neurofibromas in the periphery rarely become malignant [5,29,42]. MPNST is rare at any age and in nine combined series containing about 400 nerve sheath tumours accounted for 5% [2,6,9,13,27,28,30–32]. In a

small paediatric series of eight nerve sheath tumours only one was an MPNST [11]. As with other neurogenic tumours, the majority are situated in the posterior mediastinum. In addition to the usual symptoms of space occupation in the mediastinum (see p. 1270), MPNST may also produce the general systemic and metastatic features of any malignancy. Nausea and vomiting have been recorded in nerve sheath tumours of the vagus [34,43], and as with other sarcomatous tumours hypoglycaemia may occur. There may be extrathoracic evidence of

neurofibromatosis, such as cutaneous *café-au-lait* patches. The prognosis with MPNST is poor because of its tendency to both invade locally and metastasize.

Some MPNSTs of the mediastinum display metaplastic changes and those that contain well-developed skeletal muscle are sometimes referred to as malignant triton tumours [44].

### Autonomic nervous system tumours

These arise from autonomic nerve cells, principally the ganglia of the sympathetic chain. They span a spectrum of gradual histopathological change, from the benign ganglioneuroma to the highly malignant neuroblastoma, with ganglioneuroblastoma occupying an intermediate histopathological stage. These mediastinal sympathetic nervous system tumours tend to show greater differentiation than their retroperitoneal counterparts and as a group carry a better prognosis. The benign lesions tend to be seen in older children and adolescents, whereas the malignant lesions tend to occur in younger children. Paragangliomas, as the name suggests, arise from autonomic paraganglionic tissue.

### Ganglioneuroma

This is the most common of the three mediastinal sympathetic tumours in both adults and older children but occurs in a younger age group than nerve sheath tumours, most patients being less than 20 years of age [4]. Ganglioneuromas may be found on a chest radiograph taken for some other reason and are usually large before they cause symptoms. They contain nerve fibres and varying numbers of large mature ganglion cells. They are nearly all situated in the posterior mediastinum and in common with other neural tumours occasionally straddle the intervertebral foramen in dumb-bell fashion (see p. 1278), having similar radiographic features to the nerve sheath tumours described above (see Figs 49.2 & 49.3). Their sex incidence is equal and they are benign, encapsulated and slow-growing, lending themselves to curative surgical removal, which is indicated both for diagnostic purposes and because they may have malignant potential [2]. Although von Recklinghausen's disease is typified by the presence of neurofibromas, ganglioneuromas, like schwannomas, may also occasionally occur in this condition [2]. As with all autonomic nervous system tumours, ganglioneuromas may be metabolically active, producing catecholamines, although these hormones are less likely to produce symptoms than is the case with neuroblastoma.

Treatment is by surgical removal. Uncomplicated benign neural tumours in the posterior mediastinum are conventionally removed by posterolateral thoracotomy, although more recently 'three-hole' thoroscopic removal has been used. The latter procedure takes longer

and may be difficult with large tumours but patients tend to have a shorter hospital stay and may return to work sooner [41].

### Ganglioneuroblastoma

Mediastinal ganglioneuroblastomas are rare tumours in adults. A review of 80 cases found that 50% occurred in the first 3 years of life, while only three were found in patients aged over 20 years [45]. Their sex incidence is equal. As with neuroblastoma, the overall majority occur primarily in the adrenal medulla. Half of all mediastinal cases are diagnosed following a routine chest radiograph and the most common symptoms in the remainder are respiratory. They show histological features intermediate between ganglioneuroma and neuroblastoma, being characterized by ganglion cells with immature forms in a background of differentiating neuroblasts. Their intermediate position may result in some being classified as 'malignant ganglioneuromas' or 'differentiating neuroblastomas'. The vast majority of those occurring in the thorax arise posteriorly from the sympathetic chain. Insinuation into the intervertebral foramina in dumb-bell fashion has been described as with other neurogenic tumours (see Fig. 49.3c). They are often large pear-shaped or lobulated tumours and although the majority are encapsulated they must be regarded as malignant, with a propensity to invade locally more often than spreading by metastasis. Despite this, cure by excision is often possible and this approach, combined in some cases with radiotherapy, has achieved a 5-year survival rate of almost 90% [36]. The outlook is therefore much better than for its more malignant cousin the neuroblastoma, ganglioneuroblastoma being similar in its clinical behaviour to ganglioneuroma. Diagnosis at a young age (<3 years), a localized situation and a high degree of histological differentiation are all good predictive factors. The prognosis of mediastinal ganglioneuroblastoma is better than for abdominal forms, and if bony metastases are found a primary adrenal sympathetic tumour should be suspected.

The tumour is biochemically active in about 10% of cases, producing catecholamines whose metabolites, vanillylmandelic acid, homovanillic acid or cystathionine, may be detected in the urine. These findings may be helpful in a diagnostic sense and are also useful tumour markers, a failure of the levels to fall or a subsequent rise indicating persistent or recurrent tumour. Biochemical activity may account for the symptom of chronic diarrhoea that occurs in some cases.

### Neuroblastoma

Neuroblastomas are the third most common tumour in children after acute leukaemia and intracranial neoplasms [46]. They occur only rarely in adults, 50% presenting

within the first 2 years of life [47,48]. The sex incidence is equal [48]. Most neuroblastomas are retroperitoneal, usually occurring in the adrenal medulla, although 20% are found in the thorax and nearly all of these arise in the posterior mediastinum from sympathetic neural cells. This malignant autonomic tumour tends to be less well radiographically defined than its more benign counterparts, although in other respects its appearance is similar. In contrast with the preceding two members of this group, patients are usually unwell with anorexia, fever and cough. They occasionally display symptoms such as flushing, sweating, tachycardia, hypertension and diarrhoea that result from catecholamine synthesis, as may occur less frequently with the other members of this group of tumours [11,49]. Spinal cord compression due to dumb-bell forms may occur in common with other neural tumours and paraplegia may result [11]. Horner's syndrome, dyspnoea and dysphagia may also occur [17].

Histology shows small round immature cells that may be arranged in rosettes and there may be a variable degree of differentiation within the same neoplasm [8,48]. These tumours are highly malignant and form fleshy masses with ill-defined margins that may attain a large size. They are both locally invasive and prone to metastasize but are notable for their infrequent but well-documented propensity either to regress spontaneously or to mature into benign ganglioneuroma forms [50]. Tumour regression may even occur in the presence of metastases and probably accounts for some 'cures' [51–54]. This behaviour may be due to a phenomenon known as immunological coercion [55].

In those rare cases that occur in adulthood, the natural history of neuroblastomas is rapid in comparison with other malignancies so that survival for 2 years after diagnosis and treatment is an accepted definition of cure, provided there is no evidence of persistent or recurrent disease at that point [48]. Treatment is by surgery, to remove the tumour if possible (if not, to relieve pressure symptoms by debulking) and to obtain histological confirmation [48,56]. Radiotherapy and chemotherapy may provide additional benefit [57]. The main prognostic determinant is the age of the patient at diagnosis; a cure rate of 87% in patients aged under 2 years compared with 34% for those aged 2–12 years has been reported [48]. Localized disease carries a better prognosis, although cures may be achieved with metastatic disease provided there is no radiographic evidence of bony destruction.

### Paraganglioma

These tumours are very rare, accounting for 1–5% of neural tumours in the mediastinum [4,30,31]. They arise from autonomic paraganglionic tissue in two principal sites.

1 Most arise in the chemoreceptor tissue around the aortic

arch and pulmonary artery, which gives rise to so-called aorticopulmonary paragangliomas. These are the mediastinal counterpart of the carotid body and glomus jugulare tumour. Generally, they are hormonally non-functioning and chromaffin-negative, and in the literature are also referred to as chemodectomas, non-functional non-chromaffin paragangliomas and aortic body tumours [58]. They tend to occur in young adults with an equal sex distribution.

2 The second important site is close to the ganglia of the sympathetic chains in the paravertebral gutters, in which case they are referred to as aorticosympathetic paragangliomas [59]. These tend to be hormonally functioning and chromaffin-positive, producing catecholamines in about 50% of cases. They are sometimes referred to in the literature as chromaffinomas, functional chromaffin paragangliomas or mediastinal phaeochromocytomas, although it is now usual to reserve the term 'phaeochromocytoma' for the corresponding paraganglioma arising in the adrenal medulla [58,60].

There are a few reports of both functioning and non-functioning paragangliomas arising in relation to the heart, presumably from the cardiac plexus [61–63]. They may also very rarely occur as a primary intratracheal tumour [64]. The heart and great vessels may both be invaded and obstruction of the superior vena cava has been described [65].

Mediastinal paragangliomas have been recorded in both adults and children and in both sexes, the aorticosympathetic paraganglioma being more common in males, usually occurring in the third to fifth decades [29,66,67].

Paragangliomas are usually encapsulated, yellowish in colour and haemorrhagic; multiple tumours have been described [22,68]. Paragangliomas are highly vascular and the cellular characteristics of those occurring in the usual mediastinal sites are similar [8,22]; furthermore, the usual histological criteria for determining malignant potential cannot be readily applied to them [8,10,31] since they may recur locally or metastasize despite a benign appearance [69].

Aorticopulmonary paragangliomas rarely metastasize but tend to cause significant morbidity and mortality as a result of local spread and recurrence despite the fact that they grow only slowly [8,60]. Although they are traditionally regarded as chromaffin-negative and hormonally inactive, evidence exists to show that they may produce catecholamines in about 3% of cases [21,70].

Aorticosympathetic paragangliomas are usually hormonally active and account for about 2% of catecholamine-producing tumours, the vast majority of which are intra-abdominal, about 80% arising in the adrenal medulla [66]. Very few of these mediastinal tumours are malignant as evidenced by distant metastases [8,10,71]. They may present with episodic hypertension,

palpitations, sweating and headache, or they may not produce catecholamines in sufficient quantities to produce symptoms and are discovered as a posterior mediastinal opacity on a routine radiograph. Any suspicion that hypertension is secondary to a catecholamine-producing tumour can be substantiated by assay of blood or urine for catecholamines or their metabolites (vanillylmandelic acid, homovanillic acid or cystathionine) and by performing a phentolamine test if these other tests are equivocal [21,72]. Localization of the tumour first involves abdominal CT to exclude a primary adrenal site followed by a combination of thoracic CT and radioactive isotope scanning using a labelled norepinephrine (noradrenaline) analogue, such as <sup>131</sup>I-metaiodobenzylguanidine [66]. Thoracic aortography has also been found useful in localizing mediastinal paragangliomas because of their vascularity [36,73].

The treatment for paragangliomas is surgical and they are relatively radioresistant. Less than half of those in the aorticopulmonary area can be completely resected because of their close association with great vessels; thus they are ultimately fatal, although prolonged survival is still possible as these tumours are usually slow-growing [4,18]. The assay of catecholamine metabolites may prove a useful monitor of disease activity postoperatively in functioning tumours [71].

### Clinical problem of dumb-bell tumours

As implied above, the term 'dumb-bell' refers to the shape of neural tumours of various histological types, about 10% of which may straddle an intravertebral foramen and have both intrathoracic and intraspinal components (see Fig. 49.3c) [74]. These tumours are usually but not invariably of nerve sheath origin and are also sometimes referred to as hourglass tumours. They are important to recognize since their removal may be beyond the competence of either a thoracic surgeon or a neurosurgeon alone, the expertise of both being necessary. These tumours should be suspected preoperatively if any long tract signs are present or if the radiographs show either a widened intervertebral foramen or erosion of vertebral pedicles or lamellae. The lesions may be well shown by CT (see Fig. 49.3d), although MRI produces better images with regard to spinal cord displacement. Spinal aortography to identify the artery of Adamkiewicz (which arises from a posterior intercostal artery to supply the inferior portion of the anterior spinal artery) is recommended if the tumour is situated in the lower thoracic region in order that this vessel is not compromised during surgery.

There are considerable advantages in removing the tumour at a single combined neurosurgical/thoracic operation, with a posterior hemilaminectomy to free tumour within the spinal canal and a posterolateral thoracotomy [30,74–76]. This reduces the possibility of cord

damage caused by undue traction at the intervertebral foramen or of uncontrolled haemorrhage in the same area.

### Other mediastinal tumours of possible neural progenitor cell origin

Some migrating neural crest progenitor cells may differentiate into so-called APUD cells capable of *amine precursor uptake and decarboxylation*; tumours that may have arisen from APUD cells have been functionally grouped as APUDomas or neuroendocrine tumours. These include carcinoid tumours (of both 'typical' and 'atypical' histological types), small-cell carcinomas and large-cell neuroendocrine carcinomas. These tumours are found in the lung, where large-cell neuroendocrine carcinoma is often classified as large-cell undifferentiated carcinoma. Carcinoids may occur as primary thymic tumours, as may small-cell carcinoma, although it may be difficult to exclude spread from the lung in the latter case. Atypical carcinoid tumours are more aggressive and may themselves be mistaken for small-cell carcinoma on small biopsies due to sampling error. The capacity for these precursor cells to be chemically active accounts for the propensity of some APUDomas to be hormonally active. Melanocytes are also thought to originate from the neural crest. However, the malignant melanomas that arise from these cells are nearly always cutaneous. Although primary visceral melanomas may occur, they have not been described in the mediastinum other than in the oesophagus [77], those melanomas found in the vicinity of the mediastinum being secondary; two-thirds of patients dying of disseminated melanoma are found to have cardiac metastases [77,78].

### Disorders of the thymus

Thymic lesions comprise the largest group of anterior mediastinal masses [2,4,36] (Table 49.4). The thymus gland is a lymphoreticular organ that develops as a pair of solid buds arising predominantly from the third branchial pouch at about the sixth week of embryonic life. It migrates caudally during intrauterine development to lie

---

retrosterally in the upper part of the anterior mediastinum. Sometimes this migration is incomplete or bizarre so that it occupies a cervical or some other ectopic site [79]. The thymus has two lobes bound together by fatty tissue and contained in a capsule of loose connective tissue, from which septa arise dividing the gland into lobules. Each lobule has a cortex packed with small lymphocytes and a medulla comprising reticular cells and Hassall's corpuscles, which are zones of squamous cells surrounded by epithelial cells.

In infancy, the thymus gland is large relative to the size of the mediastinum, weighing perhaps 15 g. It doubles in size by puberty and thereafter gradually involutes, returning to its original infantile weight.

### Thymic hyperplasia

It is difficult to decide whether a thymus gland that appears to be enlarged on a chest radiograph in early childhood represents one extreme of a wide range of normal variation or whether it contains tumour (Fig. 49.4). In a number of cases coming to surgery with a preoperative diagnosis of thymoma no tumour is present but the gland is grossly hyperplastic and these patients are nearly always infants or small children [4,80]. Thymic hyperplasia may also sometimes occur in adults after successful treatment of malignant disease elsewhere with chemotherapy [81].

The histological criterion of lymphoid follicular hyperplasia of the thymus is the presence of germinal centres in the medulla [5,82]. This may occur without the gland increasing in size, whereas for true thymic hyperplasia to be present the gland itself must increase beyond the upper limits of normal for age. Thymic hyperplasia is not usually

associated with symptoms [11] but when symptoms do occur they are seen in small children and are nearly always respiratory [5,6]. The thymus may involute in childhood during any form of stress, including illness and injury, and upon recovery the phenomenon of 'rebound hyperplasia' may occur with resultant pressure symptoms [83]. Thymic involution has also been noted to be pronounced in human immunodeficiency virus infection [84]. Both thymic hyperplasia and thymoma may occur in patients with myasthenia gravis, the former accounting for 50% of thymic abnormalities found after thymectomy in one series of 10 myasthenics [85]. Thymic hyperplasia may also occur in other autoimmune disorders, such as systemic lupus erythematosus and thyrotoxicosis [80]. Thymic hyperplasia cannot normally be differentiated from an intrinsic thymic tumour by radiography, including CT [86].

When an enlarged thymus is found in infancy, steroids have been given as a diagnostic test since they may reduce the size of the hyperplastic gland. Lymphoma, which might also regress with the same therapy, is unusual before the age of 18 months [87]. When surgery has to be undertaken to relieve pressure symptoms, the histological nature of the disorder should be confirmed at operation; resection should be subtotal and confined to that part of the hyperplastic gland causing compression [5].

### Thymoma

#### Pathology

Thymoma is used to refer to tumours of epithelial origin arising in the thymus gland and containing a non-

**Fig. 49.4** Chest film of infant showing normal thymus as a right upper mediastinal mass (arrowed).

neoplastic lymphocytic component, representing functioning thymic tissue. They comprise about 20% of all mediastinal tumours and cysts and are the most common anterior mediastinal tumours [8]. Three principal histological groups were described in early classifications [88–90]: (i) the epithelial type, in which up to 80% of cells are epithelially derived (subgroups of this class are sometimes referred to as spindle cell, oval cell or epidermoid); (ii) the lymphocytic type, in which up to 80% of cells are lymphocytically derived; and (iii) the mixed or lymphoepithelial type, in which neither cell type predominates. However, these cellular characteristics do not appear to influence prognosis and although more recent histological classifications have related aggressiveness to the appearance of the neoplastic epithelial cell component and their numerical predominance over lymphocytes [91], this remains a controversial area. Prognosis appears to be mainly governed by clinical stage. Thymomas in which the capsule is intact, with no gross or microscopic evidence of invasion, tend to behave in a benign fashion and this is the case in two-thirds to three-quarters of cases [92], whereas those with gross or microscopic invasion through the capsule are regarded as malignant. These have a tendency to invade local structures and also to metastasize [93–95]. Clinical staging is therefore important and all thymomas should be regarded as potentially malignant [96–99].

### *Clinical features and diagnosis*

Thymomas may occur at any age but nearly all present in adult life and are rare before the age of 20 years. There is probably a slight overall male predominance [83,85,96]. Symptoms are present at the time of diagnosis in about 60% of patients, chest pain, dyspnoea, dysphagia and other mediastinal pressure effects having been described. There is in addition a large number of associated immune-mediated systemic syndromes, the most common of which is myasthenia gravis [92,100–103]. Pure red cell hypoplasia is unusual, occurring in about 5% of cases of thymoma [104,105]. Hypogammaglobulinaemia may also occur as may a number of other conditions, the majority of which are rare associations [92,106–108] (see Table 49.2).

The usual chest radiographic features are those of an anterosuperior mediastinal mass (Fig. 49.5) and this impression may be confirmed by CT (Fig. 49.6) [86,109]. Thymomas may rarely occur ectopically in the neck or lung or as a pleural tumour [110]. It is impossible to reliably discriminate between thymic tumour and hyperplasia by imaging techniques. Cystic changes may sometimes occur. The diagnosis of thymoma may be confirmed preoperatively by fine-needle biopsy [96], although this is not usually necessary and should be avoided if surgery is to be undertaken in any case as it runs the risk of tumour implantation [111].

### *Treatment*

The treatment of choice is surgical removal of both the tumour and the entire surrounding gland [96,112,113]. Every effort should be made to keep the capsule intact, although this may not be possible with large tumours such as that illustrated in Fig. 49.6. Surgery is by median sternotomy or thoracotomy or by a transcervical approach. Fortunately, most patients present with localized disease and routine postoperative irradiation following surgery for thymomas with an intact capsule does not improve survival, which is already good [113]. Radiotherapy is usually reserved for cases in which excision has been incomplete, and it may be a useful adjunct for these locally invasive thymomas [112,114,115]. In cases where local invasion prevents complete excision, more extensive surgical debulking procedures, as opposed to simple biopsy, appear to confer no advantage in terms of survival when both are followed by radiotherapy [116,117]. When thymoma does behave in malignant fashion it is usually by local invasion, sometimes with pleural seeding, or by local recurrence. Distant metastases, although less common, are well described and may occur as a late phenomenon, so that long-term follow up is advisable [100,118–120]. The role of chemotherapy in the management of invasive or recurrent thymoma is more controversial and has yet to be properly determined. Suffice to say that thymoma is chemosensitive and remissions have been obtained in small series with combinations of cisplatin, doxorubicin, vincristine and cyclophosphamide, sometimes as an adjunct to surgery and/or radiotherapy, although prospective randomized controlled trials are lacking [112,121,122].

### *Prognosis*

The most important factor contributing to long-term survival is complete surgical resection of tumour with an intact capsule, and when this is achieved the prognosis is excellent. An early large North American surgical series reported the survival rate for patients with non-invasive tumours to be not much dissimilar to that of the general population, whereas more invasive tumours produced a 15-year survival rate of 12.5% [123]. Series where the extent of tumour has been staged report a 5–10-year survival of over 80% for thymomas without evidence of extracapsular invasion, falling to a 10-year survival of 23% where such invasion was evident [124,125].

### **Myasthenia gravis and thymic disease**

Myasthenia gravis is an autoimmune disease, as indicated in nearly all cases by the presence of circulating autoantibodies that bind to acetylcholine receptors in the motor end-plates [126]. It is thought that T lymphocytes

(a)

(b)

**Fig. 49.5** (a) Posteroanterior film showing enlargement over left hilum. (b) Left lateral film showing lesion occupying the anterior mediastinum. On excision it proved to be a thymoma.

**Fig. 49.6** (a,b) A large anterior mediastinal mass that did not enhance with contrast on CT in a 77-year-old man. It was removed at thoracotomy and found to be a thymoma.

elaborated by the thymus interact with B lymphocytes in order to produce these antibodies, which then result in the depletion of functioning acetylcholine receptor sites at the postsynaptic membranes.

An association between myasthenia gravis and thymic tumours was recorded in 1901 [127]. The reported frequency of thymoma in patients with myasthenia gravis is variable, approximately 10–20% [5,128]. Conversely, 35–40% of patients with thymoma develop myasthenia gravis, sometimes after the tumour has been removed [98,129]. In patients with myasthenia gravis in whom the thymus is removed, the gland is seldom found to be histologically normal and thymic hyperplasia is common, particularly in younger patients, occurring in about 65% of

cases [91]. A thymoma is more likely when a patient with myasthenia gravis is older than 50 years, and this is particularly true in males [130]. A thymoma may therefore be diagnosed before, at the time of or after the onset of myasthenic symptoms. Myasthenia gravis may occur in association with any histological type of thymoma. It remains unclear if or how the pathogenesis of myasthenia gravis is related to the presence of thymomas [92]. It has been shown that the presence of striated muscle antibodies in patients with myasthenia gravis correlates with the presence of a thymoma; these antibodies were absent in over 90% of myasthenic patients without a tumour [86,131].

Thymectomy has an important role in the treatment of myasthenic patients whether a thymoma is present or not [126,132]; indeed symptomatic response may be better when the gland is found to contain follicular hyperplasia rather than thymoma or normal tissue. The results are best in younger patients with a short history of severe myasthenia, although thymectomy may be employed in any patient with deteriorating myasthenia gravis of sufficient severity despite optimal medical treatment [133,134]. Thymectomy in such patients requires close cooperation between the thoracic surgeon, neurologist and anaesthetist. The operation may be carried out successfully using a suprasternal approach, although a sternotomy is often preferred [135]. Preoperatively the dose of anticholinesterase is reduced to a minimum before complete omission in the postoperative period, when the patient is ventilated mechanically and narcotic analgesics need to be administered. Weaning from the ventilator is controlled by blood gas analyses and measurements of ventilatory capacity. Difficulties may arise in distinguishing between weakness as a result of a stress-related myasthenic crisis and a cholinergic crisis due to overdosage with anticholinesterases, the distinction being made by using the edrophonium test. Some work has indicated that high-dose corticosteroid therapy postoperatively may assist in the weaning process [136].

The standards of postoperative care of these patients have improved to such an extent that the presence of myasthenia gravis no longer adversely influences the prognosis of thymoma [96,137]; indeed, paradoxically, patients with thymomas and myasthenia gravis may survive better because their neurological symptoms result in the early detection of the tumour. Although the results from thymectomy are best in young females without tumour, those who do have thymomas may also benefit from an improvement in their myasthenic symptoms, although continued anticholinesterase therapy is the rule in this group.

### Thymic cysts

Unilocular or multilocular cystic spaces containing clear fluid or pasty material may occur in otherwise normal

thymic tissue. These thymic cysts occur with equal frequency in adults and children [138]. Some are likely to be congenital and these tend to be unilocular, being found anywhere along a line running from the angle of the mandible to the manubrium sterni. Others may be acquired, probably as a result of an inflammatory reaction in thymic tissue; these tend to be multilocular and fibrotic. Although the presence of cysts may be predicted by CT, certain differentiation from thymoma can only follow histological examination, particularly as thymic tumours of various types may cavitate [92]. Cysts are usually asymptomatic but occasionally become very large (Fig. 49.7), in which case they may produce symptoms due to mediastinal compression, including in extreme cases cardiac tamponade [139]. They are otherwise benign but because of the inevitable preoperative diagnostic uncertainty, treatment is by surgical excision. Thymic cysts in association with Hodgkin's disease are rare but well described and also tend to cause diagnostic difficulties (see p. 1290) [140,141]. It has been suggested that they may form as a result of the degeneration of treated lymphomatous tissue within the thymus but this is seemingly not always the case and their pathogenesis is uncertain.

### Other thymic tumours

The thymus gland may be the site of other tumours, although these are all encountered less frequently than thymoma. Thymic carcinoma is a rare group of tumours distinct from thymomas and seemingly unassociated with myasthenia gravis or the other immune-mediated disorders listed in Table 49.2. Various cell types have been described, including squamous, small-cell and undifferentiated carcinomas [142]. Care should be taken to ensure that these are not secondaries from lung as these and other primary tumours elsewhere may occasionally metastasize to the thymus.

Lymphomas of both Hodgkin and non-Hodgkin type may involve the thymus (see p. 1290) and are occasionally confined to it. The diagnosis can reliably be made by open or excision biopsy and treatment depends upon the extent of disease as determined by formal staging.

Carcinoid tumours may rarely arise in thymic neuroendocrine cells and the morphology of most of them is similar to that of the 'atypical' type of bronchial carcinoid tumour. They appear to be more frequent in males, are unassociated with myasthenia gravis and behave in a much more aggressive manner than thymomas, with a tendency to both recur locally and to metastasize [143,144]. A minority of them are associated with endocrine abnormalities, such as Cushing's syndrome and multiple endocrine neoplasia types 1 or 2a [145–147].

Thymolipoma (syn. lipothymoma) is a rare, benign, slowly growing tumour that has the gross appearance of a lipoma but which contains both thymic and fatty elements

[148–150]. This tumour may become enormous and is sometimes mistaken for cardiomegaly on plain films because of its propensity to mould itself about the mediastinal structures in a plastic fashion. The use of CT shows it to have the density of fat and may help to make the proper distinction.

Germ-cell tumours, both benign and malignant, may arise in the thymus gland and these are discussed in the following section. Secondary neoplastic disease in the thymus is not uncommon and may sometimes respond to surgery [151]. Occasionally ectopic parathyroid adenomas may be found embedded in the substance of the thymus (see p. 1298).

### Miscellaneous thymic disease

Thymic masses have been reported in children with Langerhans' cell histiocytosis (histiocytosis X) [152], in patients with Churg–Strauss syndrome [153] and in giant lymph node hyperplasia (Castleman's syndrome), a condition of uncertain pathogenesis that some regard as hamartomatous, the diagnosis being made after excision biopsy [154,155].

### Mediastinal germ-cell tumours

The histogenesis of mediastinal germ-cell tumours remains controversial but it seems probable that these tumours arise as a result of the proliferation of primitive extragonadal germ cells that have the potential to differentiate into various cell types of ectodermal, mesodermal and endodermal origin [36,156,157]. The anterior mediastinum is the most common adult extragonadal site for these tumours, which for some undetermined reason arise in relation to the thymus gland but which are histologically entirely distinct from thymomas. In children, extragonadal germ-cell tumours occur with greater frequency in the sacrococcygeal area [36]. Mediastinal germ-cell tumours may be benign or malignant. The terminology of germ-cell tumours is confusing because of uncertainties surrounding their pathogenesis and because of the wide histological variety that may be encountered. A plethora of synonymous terms have been used and are found scattered in the literature, nomenclature inevitably changing as wise men ponder and as the years go by (Table 49.5).

The most common mediastinal germ-cell neoplasm is mature cystic teratoma (syn. teratoma, benign or mature teratoma, dermoid cyst or tumour, teratodermoid). This tumour is benign and accounts for approximately 80% of germ-cell neoplasms, affecting both sexes equally. The term 'teratoma' was defined by Willis [158] as 'a true tumour comprised of multiple tissues foreign to the part in which the tumour is found'. This term is well entrenched in medical literature and its use will continue but is best

**Fig. 49.7** Posteroanterior (a) and left lateral (b) chest films of asymptomatic patient with huge thymic cyst.

reserved for benign tumours, the term 'teratocarcinoma' being applied to a malignant counterpart containing a combination of benign teratomatous components and embryonal carcinoma (see below and Table 49.5).

Five distinct subtypes of malignant germ-cell tumour

are described: seminoma (affecting males exclusively), teratocarcinoma, embryonal carcinoma, choriocarcinoma and endodermal sinus (or yolk sac) tumour, all of which have a strong male predilection, although rare cases have been reported in females. It is important to realize that the

histological boundaries between these tumours may be indistinct and that they may occur both in mixed and pure form. The reader should be aware that some authors have used the term 'malignant teratoma' subgenerically to include all the above malignant germ-cell tumours, although this practice is not recommended.

Both mature cystic teratomas (benign teratomas) and teratocarcinomas, in common with all germ-cell tumours, arise from immature or primordial germ cells during development. However, in the case of benign teratomas and teratocarcinomas these immature germ cells are pluripotent and still capable of producing a regionally diverse cellular output that results in different lines of embryonal tissue (epithelial, mesenchymal and neural), whereas the remaining pure histological types of germ-cell tumour (seminoma, embryonal carcinoma, choriocarcinoma and endodermal sinus tumours) possess tissue specificity [5,159]. These tissue-specific germ-cell tumours arise in an organ-formative field or 'blastoma' in which the immature germ cells are restricted to single regionally determined patterns of cellular output. Tissue-specific germ-cell tumours are all malignant and although their response to treatment is variable some are curable. The management of these neoplasms has altered significantly in the last 20 years, especially with the introduction of cisplatin-based combination chemotherapy which been found capable of curing advanced disease [160].

The histogenesis of mediastinal germ-cell tumours is controversial. Some investigators have claimed that the tissue-specific germ-cell tumours found in this site represent metastases from occult primary gonadal tumours

[161]. This is improbable for various reasons. Firstly, several studies have excluded a gonadal primary by multiple testicular sectioning [162–164]; secondly, in the case of mediastinal seminoma the disease can be cured by local therapy to the chest [165]. Furthermore, mediastinal metastases from known testicular primary seminomas are rare [166]. Extragonadal germ-cell tumours are all found near the midline and it has been suggested that they arise from primordial germ cells that fail to migrate from the urogenital ridge to the gonads during embryogenesis [162].

## Benign germ cell tumours

### Mature cystic teratoma

Mature cystic teratomas account for approximately 80% of all mediastinal germ-cell tumours and about 8% of mediastinal tumours of all types [4,5,36]. With very few exceptions indeed they are situated in the anterior or anterosuperior mediastinum, although they are less common anterior mediastinal masses than thymomas and lymphomas [167]. Rare cases have been described in the posterior mediastinum and at more than one intrathoracic site [168–170].

### Pathology

Macroscopically, benign germ-cell tumours of the mediastinum are rounded or lobulated and well-encapsulated tumours. They vary very widely in size, the average diameter in a large North American series being about 8 cm [167]. As the name suggests, they are often cystic or loculated and are commonly found at operation to be closely associated with the thymus and adherent to surrounding tissues.

Microscopically, mature tissue from all three germ layers is represented. Ectodermal elements predominate and of these the most common is skin, the cysts being lined by stratified squamous epithelium, hence the old term 'dermoid'. The other common ectodermal elements are hair and sebaceous glands (pilosebaceous units). The most common mesodermal element is smooth muscle followed by fat, cartilage and less frequently bone. Respiratory epithelium is the endodermal component most often found, followed by gut epithelium [167]. Pancreatic tissue may be found and can be enzymatically active, leading to the suggestion that digestive enzyme activity may account for the dense adhesions with surrounding tissues that characterize this tumour [171]. Islet of Langerhans components may also occur, giving mature cystic teratomas the potential to produce hypoglycaemia. A wide variety of other tissues are identifiable, including neural components and occasionally formed teeth. Calcification may also occur in the wall of this tumour (Fig. 49.8), which is

**Fig. 49.8** Posteroanterior (a) and right lateral (b) chest films of asymptomatic patient with calcified anterior mediastinal teratoma. The tumour was found to contain hair.

histologically similar to the more common mature cystic teratoma of the ovary.

Benign mediastinal teratomas may be found at any age but most series show a diagnostic peak in early adulthood [167]. They affect both sexes more or less equally [4,167,172,173], in contrast with malignant germ-cell tumours of the mediastinum that affect males almost exclusively. They are usually a chance radiographic findings in a subject with no respiratory symptoms and there is evidence that asymptomatic diagnosis has become more common [167,172]. Symptoms are more often present in

children than adults, pain in the sternal region, back or shoulder and dyspnoea with cough being usual [4,5,167,172]. Uncommonly, symptoms may occur as the result of the erosion of a teratoma into surrounding structures. Bronchial erosion may lead to haemoptysis, with the expectoration of sebaceous material or even hair (trichoptysis). The release of fatty material into the bronchial tree may cause lipoid pneumonia and its spillage into the mediastinum may incite a granulomatous reaction. Rupture into the pericardium may cause pericarditis or tamponade and rupture through the chest wall or into the

pleura, aorta and superior vena cava have been recorded [174–176], although all these complications are becoming increasingly uncommon [167]. In subjects with large tumours, evidence of obstruction of the superior vena cava, splaying of ribs, dullness to percussion, wheeze or a pulmonary systolic murmur may sometimes be found, but more commonly physical examination reveals no localizing signs.

### *Investigations*

Chest radiography characteristically shows a well-circumscribed or lobulated anterior mediastinal mass that may extend into one or other lung field (see Fig. 49.8). Flecks of calcification in the wall or substance of the mass and sometimes bone or tooth may be found in 15–40% of cases [167,172,177]. The presence of an air–fluid level may indicate a bronchial communication. Ultrasound examination or CT may show cystic changes with areas of fat density [178], although the diagnosis can only be established with certainty by pathological examination after surgical removal.

### *Treatment*

The treatment of choice is total excision via either thoracotomy or sternotomy. This operation is advisable because of the diagnostic uncertainty that would otherwise exist and also because of the possibility of complications, including very rare malignant change [179,180]. Although these benign germ-cell tumours may be ‘shelled out’ easily [5], removal is often difficult because of dense adhesions between the lesion and surrounding structures, such as the pericardium, lung, great vessels, thymus and chest wall [172]. Lobectomy may be necessary when a teratobronchial fistula is present. Surgical removal achieves total cure even if excision has been incomplete because of adherence to mediastinal structures [172].

### **Immature teratoma**

Immature teratoma of the mediastinum may be regarded as the potentially malignant counterpart of mature cystic teratoma. It contains immature elements of the three germ layers but unlike teratocarcinoma (see below) contains no component of embryonal carcinoma. The behaviour of this tumour is age-dependent (parallels with neuroblastoma) so that in infancy and early childhood it acts mainly as a space-occupying lesion, whereas after the age of about 14 years it behaves as a malignant tumour invading adjacent structures and metastasizing widely [159].

### **Malignant germ cell tumours**

Approximately 20% of germ-cell tumours of the medi-

astinum are malignant [5]. Therapeutically and prognostically it is very important to distinguish between those malignant germ-cell tumours that are pure seminomas and those that contain any non-seminomatous elements [165]. Seminomas and non-seminomatous germ-cell tumours are therefore considered separately.

### **Non-seminomatous tumours**

#### *Classification*

Immature teratoma, which straddles both groups, has already been discussed above and this section therefore includes (i) teratocarcinoma (syn. malignant teratoma), which comprises embryonal carcinoma surrounding foci of benign teratoma with elements of immature teratoma, and (ii) three other tumours of more specific cellularity: choriocarcinoma (syn. trophoblastic teratoma), endodermal sinus (or yolk-sac) tumour and embryonal carcinoma, the latter being the least differentiated of this group but having the potential to transform into the other non-seminomatous cell types. Many malignant germ-cell tumours contain mixtures of the specific cell types within this group and one or more of the non-seminomatous tumour cell types may also occur in combination with seminomatous elements, so-called mixed germ-cell tumours in which all individual cell types should be specified. Occasionally, sarcomatous elements may occur in malignant mediastinal germ-cell tumours, a finding that worsens the prognosis as these components are less susceptible to chemotherapeutic agents [181].

#### *Clinical features*

Non-seminomatous germ-cell tumours of the mediastinum occur most commonly in the third decade of life and are extremely rare in females [5,165]. With the exception of immature teratoma in infancy and early childhood, they behave in a highly malignant fashion, with local invasion and a tendency to metastasize, and are usually associated with symptoms at the time of diagnosis. Chest pain, cough and dyspnoea are common and may be accompanied by systemic symptoms [5,165]. Obstruction of the superior vena cava may occur. Gynaecomastia is commonly present in these patients, especially in those with choriocarcinoma, presumably due to the elaboration of human chorionic gonadotrophin (hCG) from trophoblastic elements of the tumour [182,183]. There is also a well-recognized association between the development of malignant non-seminomatous germ-cell tumours and the presence of Klinefelter’s syndrome; indeed germ-cell tumours may be 30–40% more common in this group of patients than in the population as a whole [184–188]. There is also an association between non-seminomatous mediastinal germ-cell tumours, particularly those with a

yolk-sac component, and various haematological malignancies including acute leukaemias and malignant histiocytosis [189,190].

### *Investigation*

Chest radiography shows an anterior mediastinal mass that may cause mediastinal displacement and there may be evidence of metastatic intrathoracic spread. A more accurate disposition of the tumour is demonstrated by CT, which shows the neoplasm to be more solid than mature cystic teratoma but with areas of heterogeneity, corresponding to haemorrhage and necrosis. The tumour is also less likely to contain areas of fat density than benign teratoma [191]. An accurate diagnosis may be obtained by the submission of a generous surgical biopsy in order to facilitate identification of the tumour type and to enable immunohistochemical and genetic studies to be carried out. Occasionally such genetic studies reveal a chromosome marker that confirms the germ-cell origin in a tumour of otherwise uncertain histology, a finding that may be therapeutically important in terms of indicating appropriate cisplatin-based chemotherapy [192]. CT- or ultrasound-guided percutaneous needle biopsy may result in an inaccurate diagnosis in these tumours.

Diagnosis is also assisted by the detection of two protein tumour markers in the patient's serum [193]:

1 the  $\beta$  subunit of hCG may be detectable at any surgical stage and in 40–60% of patients with metastatic non-seminomatous malignant tumours but only 15–20% of metastatic seminomas;

2  $\alpha$ -fetoprotein (AFP) may also be present at any surgical stage and in 40–60% of non-seminomatous metastatic malignant tumours [160,183,194,195].

AFP has never been detected in pure seminomas and its presence in a patient with a germ-cell tumour is always taken to indicate a non-seminomatous element, a finding of crucial therapeutic and prognostic importance. Of the non-seminomatous germ-cell tumour components, AFP is specifically produced by embryonal carcinoma and endodermal sinus (yolk-sac) tumours. AFP concentrations may also be raised in inflammatory or toxic liver damage, hepatomas and other gastrointestinal tract tumours [196]. hCG is not as specific but high levels are suggestive and one or other, or both, of these two markers is present in about 90% of malignant non-seminomatous germ-cell tumours. Serum lactate dehydrogenase may also be raised in both seminomatous and non-seminomatous germ-cell tumours [160].

### *Treatment and prognosis*

The extent of disease is determined as for seminoma. The possibility of spread from an occult testicular tumour is considered in all extragonadal presentations of malignant

germ-cell tumour since a testicular primary may be very small even though metastases have occurred (see section on seminoma). Unfortunately, invasion of adjacent mediastinal structures or metastases are usually present at the time of diagnosis in non-seminomatous germ-cell cancers and surgery has ceased to be a primary treatment, complete removal having been found to be most unusual though not unheard of [165]. Patients with mediastinal non-seminomatous germ-cell cancer are considered 'poor-risk', with a low likelihood of cure, and are usually relatively insensitive to radiotherapy, the mainstay of treatment being chemotherapy [160]. The management of non-seminomatous germ-cell tumours, as with seminomas, has been the subject of much research and collaborative effort and is a matter for the expert.

Trials to improve the effectiveness of treatment in poor-risk germ-cell cancer are ongoing, one current approach comprising four cycles of conventional-dose bleomycin, etoposide and cisplatin. Some patients die within a year, although success has been achieved using cisplatin-based chemotherapy as primary treatment [197,198]. One early study achieved a median survival time of 14 months using this approach provided that cisplatin and bleomycin were included in the regimens [165]; more recent series have reported a 2-year survival of 53% (median 28 months) in 64 patients [197] and a median survival of 55 months in a small group of 11 patients [198]. Surgery may have a role in debulking residual disease after chemotherapy, once normal levels of tumour markers have been achieved. Although these tumours still carry a poor prognosis compared with their testicular counterparts, about half should be cured with modern chemotherapy [199].

The serum levels of tumour markers are used as an essential tool in monitoring the response of disease to treatment, AFP and hCG being measured and monitored before, during and after treatment. A sustained rise or increasing levels of either AFP or hCG or both may be taken to indicate active disease, even in the absence of symptoms, signs or radiographic change, and may lead to therapeutic intervention. The levels decline after treatment and a failure to do so is indicative of residual active disease [200]. Furthermore, there is evidence to suggest that a bulky tumour need not indicate a poor prognosis in the absence of high tumour marker levels [201].

## **Seminoma**

### *Clinical features*

Seminoma (syn. germinoma, dysgerminoma) is the most common single malignant mediastinal germ-cell tumour, accounting for approximately half of all these neoplasms [165]. They affect young men, 95% occurring between the ages of 20 and 40 years [202], so that sperm banking should be considered prior to chemotherapy. Mediastinal

seminomas almost always arise within the thymus gland. They are histologically indistinguishable from testicular seminomas. Only one-third of patients are asymptomatic, in contrast with benign mediastinal germ-cell tumours, the most common symptom being chest pain [165,202]. Dyspnoea and obstruction of the superior vena cava sometimes occur. It is not unusual for these tumours to metastasize.

### Investigation

The chest radiograph shows a lobulated, usually non-calcified anterior mediastinal mass (Fig. 49.9). More accurate disposition of the tumour is confirmed by CT, which often shows the neoplasm to be large, lobulated, more solid and less likely to contain fat than benign mature teratomas [191]. Diagnosis is established by the removal of a generous piece of tumour in order to identify the tumour type and to enable immunohistochemical and genetic studies to be carried out. CT- or ultrasound-guided percutaneous needle biopsy may result in an inaccurate diagnosis in these tumours. Further evidence that the tumour is free of non-seminomatous germ-cell tumour elements, whose presence would alter management, is provided by a normal serum level of AFP. hCG is also usually absent, occurring in only 7–10% of pure seminomas and 15–20% of patients with metastatic seminoma [160,165]. Other tumour markers for seminoma, such as serum lactate dehydrogenase, are being evaluated but are less specific, also being found in non-seminomatous germ-cell tumours. For practical purposes, a seminoma is only diagnosed if the histology shows pure seminoma and if the serum level of AFP is not raised [203].

The possibility of metastasis from a testicular tumour should always be considered in any malignant germ-cell tumour, although primary mediastinal seminoma is a sufficiently well-recognized entity for surgical exploration of the testis to be unnecessary provided that (i) physical examination provides no evidence of testicular swelling or atrophy, (ii) ultrasound examination of the testes is normal and (iii) no evidence of retroperitoneal lymph node involvement is found by CT of the abdomen and pelvis [163,164,166].

The ultrasonographic findings of testicular germ-cell tumour include one or more discrete hypoechoic masses or more diffuse abnormalities with microcalcifications.

### *Treatment and prognosis*

Seminomas carry a better prognosis than non-seminomatous germ-cell tumours and it is important to make the diagnosis accurately. As with germ-cell tumours in general, the management of seminomas has been the subject of national and international collaborative research and is a matter for the expert. Although seminomas are highly radiosensitive (and indeed complete cure may be obtained by radiotherapy) [165,166], the treatment of choice for seminoma has shifted from radiotherapy to chemotherapy, irradiation tending to be reserved for bulky tumours. Although cure has been achieved in the past when all gross evidence of tumour has been removed by surgery [5], operative attempts to remove tumour other than for histological diagnosis have generally been incomplete and are usually no longer indicated. Currently, chemotherapy takes the form of four cycles of standard etoposide and cisplatin or three cycles of bleomycin, standard etoposide and cisplatin [160]. Patients with an incomplete remission and those who relapse may be given second- and third-line 'salvage' chemotherapy, from which a significant number of cures have been obtained [160]. Such treatment may include high-dose chemotherapy with autologous bone marrow (stem cell) rescue [204]. A 2-year survival rate of 86% was reported in a series of 23 patients with pure mediastinal seminomas, most of whom were treated (between 1983 and 1990) with cisplatin-based chemotherapy, although some had been primarily treated with radiotherapy [197]. In a small series of seven patients with pure mediastinal seminomas treated with cisplatin-based combination chemotherapy and in some cases additional radiotherapy, 100% disease-free survival was reported at a median follow-up time of 41 months [198]. With modern cisplatin-based chemotherapy and radiotherapy, long-term survival or cure can be expected in around 80% of this group [199].

## **Other mediastinal tumours and tumour-like conditions**

### **Mediastinal lymphoma**

Any type of lymphoma can involve any lymph node, including those in the mediastinum as well as those radiographically more obvious nodes in the hila. The thymus gland may also be the seat of a lymphoma, although whether the disease originates in this site is not clear. Lymphomatous involvement of the lungs is described in Chapter 42. The mediastinum is involved in over 50% of patients with Hodgkin's disease [205]. Mediastinal Hodgkin's disease is considered 'massive' if the ratio of the maximal horizontal width of the mediastinal mass to the maximum intrathoracic diameter on a standard chest radiograph exceeds one-third [205]. Most cases of

Hodgkin's disease found in the mediastinum are of the nodular sclerosing type. The correct diagnosis (as with other mediastinal tumours) is clearly important since lymphomas are eminently treatable and in many cases curable. The temptation to establish the diagnosis of a mediastinal tumour by CT- or ultrasound-guided percutaneous needle biopsy, although attractive in avoiding a more invasive surgical biopsy, runs the risk of misdiagnosis in cases of lymphoma, for which the pathologist requires a block of tissue so that a full morphological and immunohistochemical analysis can be carried out (as is the case with germ-cell tumours, see above). Failure to do this may result in some treatable non-Hodgkin lymphomas being mistakenly labelled as anaplastic carcinomas [206,207], with prognostic consequences.

Treatment may be with intensive chemotherapy regimens or primary radiotherapy or both, depending on the type, stage and bulk of the disease [205,206,208,209], and is a matter for experts in this field. Management dilemmas may sometimes be created by the persistence of cysts in the substance of the thymus following the treatment of thymic lymphoma, as there may be uncertainty about whether such cysts represent residual or recurrent disease or indeed whether they are benign. In such cases it is probably best to withhold further treatment unless pathological confirmation of active disease is obtained [141]. Similar dilemmas arise when imaging shows residual opacities in lymph node areas following treatment; indeed these are found in over 60% of patients with mediastinal disease, particularly when the original lymph node mass was large [205]. Persistent gallium isotope uptake or positron emission tomography may be helpful in distinguishing disease activity from non-malignant tissue in doubtful cases and may lead to further biopsy [205,206,209].

Patients with stage II massive mediastinal Hodgkin's disease have relapse rates of 50–74% when treated with nodal radiotherapy alone, while chemotherapy alone has been found to have relapse rates of 33–50% [205]. Improved survival may be obtained by using a combined approach, and some workers have favoured chlormethine (mustine)/vincristine/procarbazine/prednisolone (so-called 'MOPP') or doxorubicin/bleomycin/vinblastine/dacarbazine (DBVD) followed by radiotherapy [205]. The prognosis for non-Hodgkin's lymphoma varies according to the histology and stage. For well-localized high-grade tumours, disease-free survival rates of 60–80% may be achieved at 5 years. Where disease is widespread and treated with chemotherapy, the rates are 30–40%. Low-grade non-Hodgkin lymphoma runs a more indolent course, with a median survival of 7–8 years [210]. The freedom-from-relapse rate at 5 years for primary mediastinal large-cell and immunoblastic lymphoma was found to be 45% in a study of 57 patients, and the presence of pleural effusion at presentation was associated with an extremely poor outcome [209].

### Mediastinal amyloid

Amyloidosis is the term used for a group of diseases characterized by the extracellular deposition of fibrillar proteins consisting of fragments of immunoglobulin light chains. There have been a number of case reports of tumorous or lymph node deposits of amyloid in the mediastinum. The diagnosis of this very rare condition can only be made by histological examination of biopsy material, which shows a characteristic amorphous eosinophilic substance that stains positive with Congo red and which shows characteristic apple-green birefringence under polarized light microscopy [211,212]. An aspirate of subcutaneous abdominal fat may also stain similarly if other involved tissue is inaccessible. Monoclonal proteins are usually detected on electrophoresis of serum or urine. The prognosis depends upon the type and extent of disease, length of survival varying from months to years. Treatment is generally supportive but experience is accumulating with the use of colchicine, melphalan and, in certain cases, organ transplantation [213].

### Mediastinal mesenchymal tumours and tumour-like lesions

Mediastinal mesenchymal (connective tissue) tumours form a diverse group of rare neoplasms that account for only about 6% of mediastinal tumours [18]. They arise from mesenchymal or connective tissue elements, including lymphatic tissue, blood vessels, fat, smooth and skeletal muscle [92]. Some are regarded as hamartomatous malformations, others as true neoplasms, either benign or their malignant (sarcomatous) counterpart. Their morphology may be heterogeneous, depending on the differentiation of the primitive mesenchymal cell, so that different cell lines are sometimes found in the same tumour. The precise diagnosis depends upon histological examination following surgical biopsy or excision, only fatty tumours lending themselves to more confident pre-operative diagnosis because of their characteristically low attenuation values on CT.

Benign tumours such as lipomas are usually asymptomatic findings but may produce compressive symptoms and signs if they attain a large size. Their malignant counterpart, the liposarcoma, is more likely to produce dyspnoea and chest pain but may also be asymptomatic at the time of diagnosis [214]. This may arise in any mediastinal compartment but possibly favours the anterior mediastinum, where it may also arise within the thymus [215]. Surgical excision may be curative but these tumours have a tendency to run an aggressive course with local recurrence, although distant metastases are not a common feature.

A series of 10 surgically resected malignant smooth muscle tumours (leiomyosarcomas) reported seven in the

posterior and three in the anterior mediastinum. Most of those patients with posterior lesions were asymptomatic, whereas the anterior ones tended to produce compressive symptoms. Survival was related to histological grade and surgical staging [216]. Malignant skeletal muscle tumours (rhabdomyosarcomas) may arise in the anterior mediastinum of younger adults and behave in a highly aggressive manner [217]. Rhabdomyosarcomatous elements may also occur focally within non-seminomatous germ-cell tumours [199].

Benign tumours of blood vessels (haemangiomas) tend to be diagnosed in children and young adults but may occur at any age. They favour the anterior mediastinal compartment and range in size from small to very large. Two types are described: one is more solid and lobular, the so-called capillary haemangioma; the other, known as cavernous haemangioma, has larger dilated vascular spaces. The most common presenting symptoms in a series of 18 cases were dyspnoea, cough and chest pain [218]. These tumours tend to enhance on CT [219]. Haemangiosarcoma is an even rarer tumour in this location and has been treated by radical excision and postoperative radiotherapy [220].

Mediastinal lymphangiomas are probably hamartomatous malformations rather than true neoplasms and may result from a localized failure of the developing lymphatic system to communicate with its venous counterpart. Cystic forms of lymphangioma (so-called cystic hygroma, see below) most commonly arise in the neck of infants and sometimes extend into the superior mediastinum [221]. Solitary lymphangiomas arising exclusively in the mediastinum rather than extending from the neck are most commonly found in adults [221]. They are benign localized lesions up to several centimetres in diameter, comprising endothelial-lined spaces with a supporting connective tissue stroma that may contain smooth muscle. They are morphologically similar to haemangiomas but may contain straw-coloured fluid or chyle rather than blood [221]. They may occur anywhere in the mediastinum and although benign can infiltrate along tissue planes in a serpiginous fashion, proving difficult to remove completely at surgery. They may produce symptoms as a result of pressure on surrounding structures and are sometimes complicated by chylous pleural effusions but are often completely asymptomatic [16,221]. Lymphangiomas sometimes occur in multiple form as part of a generalized maldevelopment of the lymphatic system, so-called lymphangiomatosis, in which the tumours may be found in the mediastinum and the lungs as well as in abdominal viscera and the retroperitoneal space [222–225]. Lymphangiomatosis may also involve bones, producing cystic endothelium-lined spaces [222].

Mediastinal lymphangiomas should not be confused with lymphangiomyomas (previously called lymphan-

giopericytomas), which are true neoplasms seen only in females, the tumour consisting of intimately mingled lymph vessels and smooth muscle elements with particular immunohistochemical characteristics [92]. Lymphangiomyomas may occur in localized form, often in association with the thoracic duct or its tributaries in the mediastinum or retroperitoneal space and sometimes result in chylothorax. There is a generalized or systemic form of this condition known as lymphangiomyomatosis (or lymphangioleiomyomatosis) that occurs in postpubertal women. This condition is characterized by a proliferation of immature smooth muscle derived from associated lymphatics [226,227]. This smooth muscle infiltrates the walls of alveoli and bronchi with resultant air trapping and impaired gas transfer that may mimic emphysema. These women tend to present in their thirties with slowly progressive breathlessness and radiographic and CT changes that alter from a reticular infiltrate to 'honeycombing' with diffuse cystic change, so that pneumothoraces are a common feature [228]. The myoproliferative process may involve pulmonary blood vessels and lymphatics, resulting in haemoptysis and chylothorax respectively (see Chapter 42). There are close histological parallels between lymphangioleiomyomatosis and the

pulmonary manifestations of tuberous sclerosis, although this hereditary condition affects both sexes and also has cutaneous and cerebral manifestations. The pathogenesis of lymphangioleiomyomatosis remains obscure but the condition is probably a hamartomatous malformation of smooth muscle [229].

Cystic hygromas rarely develop in the superior mediastinum but more usually present as a poorly defined swelling in the neck, usually posterior to the sternomastoid muscle. However, these may extend into the mediastinum in about 10% of cases [221,230,231]. Even in this situation they are rare in adults, the vast majority being diagnosed within the first 2 years of life. They are thin-walled endothelially lined cystic tumours that contain lymph and are usually multilocular. The term 'cystic hygroma' is used synonymously with 'cystic lymphangioma' [232] and they are regarded as congenital hamartomatous malformations that may arise as a result of a bud of lymphatic tissue becoming pinched off during early development [233]. They are soft and yielding structures and although they may increase in size in adults as a result of the accumulation of lymph and the enlargement of their spaces, they do not usually produce pressure symptoms unless distended by haemorrhage into the cyst (Fig. 49.10)

**Fig. 49.10** Barium swallow in patient who presented with stridor showing mediastinal displacement to left. At operation, the tumour proved to be a cystic hygroma into which an acute bleed had occurred.

or by infection [234]. The diagnosis in adults usually follows the finding on the chest radiograph of a well-defined, rounded, homogeneous density with a sharp border in the superior mediastinum. CT shows the lesion to be cystic and of low density [234]. Treatment is by surgical excision, which may be difficult as cystic hygromas tend to mould themselves to the contours of the mediastinal contents so that a plane of cleavage may not be easy to establish [5,235].

## Developmental mediastinal cysts

Congenital cysts of the mediastinum account for an average of 16% of all mediastinal cysts and tumours [2–4,6,10,30,36]. Foregut duplications are the largest group followed by pleuropericardial cysts. Congenital cysts may also occur in the thymus as described above (see Fig. 49.7) and also in relation to the thoracic duct and occasionally in ectopic thyroid or parathyroid tissue (see below).

### Foregut cyst or duplication

#### *Classification*

The term 'foregut duplication' (or reduplication) may be applied to cysts, diverticula and fistulae that have resulted from developmental malformations of the primitive foregut in the embryo. Such cysts therefore contain tissues derived from primitive endoderm and mesoderm. The term 'bronchogenic cyst' is often used synonymously with 'bronchial cyst' for foregut duplications that are clearly related to the airways, especially the trachea and main bronchi, a common site being posterior to the carina. Those closely related to the gut are variously referred to as gastric, enteric or gastroenteric cysts, depending on their principal histological constituents; those where there is an associated vertebral abnormality are often called neurenteric cysts.

#### *Pathogenesis*

The pathogenesis of foregut duplications is incompletely understood, although several different mechanisms are likely to be operative [236].

1 One possible mechanism is the defective separation of the tracheobronchial bud from the foregut proper so that a bud or diverticulum becomes pinched off, creating a cystic space that may be found between the trachea or a major bronchus and the oesophagus or stomach. Such a cyst may be connected by a fibrous strand to the gut, the tracheobronchial tree or both and may be referred to as a tracheobronchial foregut duplication. When one of the connecting strands remains patent, then the 'cyst' is in fact a diverticulum of either the gut or the tracheobronchial tree; if both

connections are patent, then a tracheobronchial fistula results.

2 A second mechanism may involve the defective coalescence of chains of vacuoles that form during epithelial proliferation within the developing tracheobronchial tree, giving rise to solitary or multiple intralobar bronchogenic cysts or oesophageal cysts embedded in the oesophageal wall.

3 A third mechanism may give rise to so-called neurenteric cysts, in which a tract of abnormal development runs between a part of the upper gastrointestinal tract and the skin surface, usually over the upper thoracic spine. This anomaly is presumably initiated at an embryonic stage when the cellular precursors of the spine and the upper gastrointestinal tract are still contiguous, the neural tube and foregut being connected by the primitive neurenteric canal [237]. The persistence of this may result in a fistulous tract running from the alimentary canal to the surface of the skin [238]. This canal or its remnants may divide both the spinal cord and a corresponding vertebral body and has therefore been referred to as the split notochord syndrome [239]. Reabsorption of parts of this fistula may give rise to incomplete forms of the split notochord syndrome but upper thoracic spine anomalies are a common feature.

Intrathoracic foregut duplications may be intrapulmonary or extrapulmonary and, as suggested above, usually occur in relation to the oesophagus, the trachea or a major bronchus. They are reportedly more common in the right hemithorax than the left [5,236,238,240]. They are more likely to be diagnosed in infancy rather than adult life because their expansion in a limited space exerts pressure effects on surrounding structures [36,241].

#### *Pathology*

Macroscopically, foregut duplications appear as rounded or oval saccular structures. Bronchogenic cysts are usually spherical and thin-walled, containing gelatinous mucoid green/blue material with an average diameter of about 4 cm [92]. Their wall may be lined by ciliated columnar epithelium or pseudostratified epithelium of respiratory type and may contain bronchial glandular elements as well as cartilage and neural tissue. These walls may undergo calcification. Oesophageal cysts may be found in the wall of that viscus and characteristically contain a double layer of smooth muscle in their own wall. They are occasionally tubular, traversing the long axis of the entire thorax and may contain thick mucus [238]. Rarely there may be a communication with the parent organ and exceptionally they may be multiple [5,238,242]. Gastroenteric and neurenteric cysts usually occur in the posterior mediastinum paravertebrally and are associated with vertebral, spinal cord and skin abnormalities, the cysts sometimes communicating with the skin surface through a

spina bifida [238,239,243]. Microscopically, gastroenteric and neurenteric cysts have walls simulating stomach or intestine. Those with gastric features may contain parietal cells and the latter may form peptic ulcers [241]. Some cysts contain ectopic pancreatic tissue [244]. The histological findings are not always specific enough to allow differentiation between these various foregut duplications and overlap may occur.

### *Clinical features*

The majority of children with intrathoracic foregut cysts are symptomatic, with dyspnoea, stridor or persistent cough; one-third of those with neurenteric cysts may present with a motor or sensory neurological deficit, back pain or an abnormality of gait resulting from spinal cord involvement [241,245]. In adults the majority of foregut cysts are asymptomatic and are chance radiographic findings on a routine chest film [246]. Large cysts may cause cough, stridor or dysphagia. Complications include recurrent lower respiratory tract infection due to pressure, and perforation due to either infection of the cyst itself or peptic ulceration in the case of gastric or gastroenteric cysts. Perforation may occur into the lung, pleural or pericardial cavities, causing haemoptysis, empyema or septic pericarditis [247,248]. Adenocarcinoma has been reported in a foregut cyst but is an exceptional complication [249,250].

### *Chest radiography*

The chest radiograph may show a rounded opacity sometimes with a hair-line margin (Fig. 49.11). The majority exceed 5 cm along their longest axis [5]. The cyst occasionally contains a fluid level, indicating communication with the respiratory or gastrointestinal tract [251]. Calcification is sometimes seen in the wall of the cyst, if not with plain radiography then with CT. The presence of spinal abnormalities, such as fused vertebral bodies or a dorsal scoliosis, implies that the cyst is neurenteric and is an indication for spinal MRI, which may reveal an intraspinal cystic abnormality even in the absence of neurological symptoms or signs [241,243,252]. Radioactive technetium-99m scanning may be positive in cysts lined by gastric mucosa [253].

### *Treatment*

Treatment is by surgical excision, which both establishes the diagnosis and avoids the possibility of future complications. In an acutely breathless child, emergency needle aspiration of a tense cyst offers temporary relief. When a coincidental intraspinal cystic component is discovered, neurosurgical removal is recommended because of the possible subsequent development of a neurological deficit [241]. Ulceration of a mediastinal cyst into the lung may necessitate both excision of the cyst and lobectomy. The

**Fig. 49.11** Large right-sided foregut cyst that caused tracheal compression and stridor.

prognosis for these cystic malformations is generally excellent, although incompletely resected foregut duplications may recur.

### **Pleuropericardial cyst**

Synonyms for pleuropericardial cysts abound and include pericardial cyst, coelomic cyst, springwater cyst, serosal cyst, mesothelial cyst, parapericardial cyst, simple cyst and hydrocele of the mediastinum! They are usually reported in surgical series as the second most common form of mediastinal cyst after foregut duplications, although it is possible that they may be seen more commonly in a physician's practice. Le Roux [254] estimated that one pericardial cyst was diagnosed per year for every 100 000 of the population studied.

### **Pathology**

Pleuropericardial cysts are usually considered to be developmental anomalies whose origin is uncertain. It has been suggested that they arise as a result of the persistence of the ventral parietal recess of the primitive intraembryonic coelomic cavity, from which the pericardial, pleural and peritoneal cavities develop [255,256]. The coelomic cavity itself may be formed by the fusion of multiple disconnected lacunae in the primitive mesenchyme and a failure of one of these lacunae to fuse with the continuum may result in the formation of a pleuropericardial cyst [257].

Of these cysts, 70% occur in the right cardiophrenic angle and are usually situated anteriorly, tending to be loosely adherent to the pericardium and diaphragm [258,259]. Most of the remainder occur in the left cardiophrenic angle but are occasionally found in unusual locations such as the superior or posterior mediastinal compartments [260–262].

The sex incidence is approximately equal and they may occur from infancy to old age [255]. They may vary widely in size, from 5 to 25 cm in diameter [263]. They are soft and are usually unilocular, their walls being thin, consisting of a single layer of flattened mesothelial cells supported by a connective tissue stroma [255,258]. They characteristically contain crystal-clear 'springwater', although this is occasionally a more brackish yellow. The fluid is acellular and contains little protein, having the features of a transudate. They are usually truly cystic, although a small proportion communicate with the pericardial or pleural cavities via a tubular connection and in such cases are therefore diverticula [5,255].

### **Clinical features**

Between 60 and 80% of pleuropericardial cysts are asymp-

tomatic, presenting as a chance chest radiographic finding [5,255,258]. When symptoms are a feature, chest pain is most common, occurring in about 20% of cases. Pericardial cysts may compress the right middle lobe bronchus, causing cough and dyspnoea but this is unusual as they are under low pressure.

### **Diagnosis and treatment**

The provisional diagnosis is usually made following posteroanterior and lateral chest radiographs on the basis of a sharply demarcated, smooth-edged, rounded 'mass' shadow of uniform density situated anteriorly in the right, or less commonly the left, cardiophrenic angle and abutting the heart, diaphragm and anterior chest wall (Fig. 49.12a). Pericardial cysts have been observed to increase in size over a number of years on serial radiographs and a previously normal chest film does not exclude the diagnosis [255,258,264]. It is unusual for the rim of the cyst, which is very thin, to calcify. The absence of pulsation may be noted at fluoroscopy, as may the propensity of the cyst to alter shape during respiration and with postural change [257]. Echocardiography confirms the cystic nature of the lesion by showing a typical echolucent area that is anatomically distinct from the cardiac cavities [264]. CT shows a mass of fluid density that does not enhance following intravenous contrast [265–267] (Fig. 49.12b). The presence of a fluid-containing cyst may be confirmed by fine-needle thoracentesis of the lesion under ultrasound or CT control [268].

The most usual differential diagnoses are a prominent pericardial fat pad, an anterior diaphragmatic eventration and a diaphragmatic hernia through the foramen of Morgagni, which may contain gut or extraperitoneal fat. Less commonly, a pericardial cyst may be mimicked by a ventricular aneurysm and rarely by a rounded tumour of the middle lobe, pleura or diaphragm, or by a hydatid cyst, all of which may abut the heart or occupy the cardiophrenic angle. The differential diagnosis is much wider where a pericardial cyst is atypically situated elsewhere in the mediastinum or hilar regions.

The diagnosis may be confirmed and treated in symptomatic patients at thoracotomy or video thoracoscopy, in which case the pericardial cyst is excised [5,255,269,270]. This course of action removes doubt about the validity of the preoperative diagnosis, which has been shown to have been misplaced in earlier literature in up to 50% of cases [258]. Nowadays the diagnosis is more usually made using non-invasive imaging techniques and asymptomatic patients are managed conservatively [257,258,271,272]. CT may not always reliably differentiate between pericardial cysts and other cystic or low-density lesions, so that the uncertainty and anxiety of extended follow-up may be best removed by active surgical inter-

(a)

(b)

**Fig. 49.12** (a) Characteristic appearance of pericardial cyst in right cardiophrenic angle. (b) CT shows pericardial cyst at right cardiac border anteriorly.

vention [255,272,273]. Aspiration, although usually safe, carries a small risk of dissemination of disease or anaphylaxis in the rare case of hydatid cyst, which should be serologically excluded prior to needling if this is a concern. When aspiration is used the fluid often reaccumulates [258].

The prognosis following surgical excision is excellent and there have been no reported cases of malignant change [255]. Symptoms are not always relieved by cyst excision, implying that they are often coincidental [5].

### Thoracic duct cyst

These solitary cysts are a very rare intrathoracic finding and probably arise as a result of a developmental defect or weakness in the wall of the thoracic duct, of which they are really diverticula. They may be found accidentally on a routine chest radiograph that reveals a posterior mediastinal mass shadow, although symptoms of oesophageal or tracheal compression may sometimes be produced [274–276]. Ascending lymphangiography may be diagnostic if the condition is considered preoperatively [275]. Treatment is by surgical excision, which confirms the diagnosis and which should be curative. At operation a thin-walled, unilocular ‘cyst’ that contains chyle and which communicates with the thoracic duct is found. Chylothorax is a potential complication of operative treatment, although it should be possible for the surgeon to avoid this

by identifying and ligating the neck of the diverticulum as it arises from the thoracic duct [276].

### Retrosternal goitre and associated lesions

An extension of a cervical goitre into the thorax is probably the most common mediastinal tumour [5]. However, its true proportion is unknown as it is often managed by general rather than thoracic surgeons and its frequency therefore tends to be underestimated in surveys of mediastinal masses that appear in the thoracic literature. It is reported in one large series that 6% of cervical goitres have a retrosternal extension [277], whereas the finding of a retrosternal goitre in the absence of a goitre in the neck is rare.

#### Developmental features

Enlarging cervical goitres may expand into the thorax as a result of the anatomical restraints imposed by the cervical musculature and fascia, and also as a consequence of the effects of gravity and negative intrathoracic pressure. The usual pathological change in such intrathoracic extensions is nodular hyperplasia. Less commonly, thyroid tissue may find its way into the mediastinum during embryological development. A hollow diverticulum arises from the floor of the primitive pharynx in the fourth week of life at a site marked in the adult by the foramen caecum of the

tongue. The thyroid rudiment is formed in this process and it migrates caudally on a tube that becomes the thyroglossal duct. During the unfolding of the embryo, this rudiment may be dragged caudally in relation to the primitive aorta so that truly ectopic thyroid tissue may be found anywhere along a track extending from the tongue through the superior and anterior mediastinal compartments to the pericardium and heart [278,279].

### *Pathology*

Macroscopically, intrathoracic goitres nearly always extend from the lower pole of a lateral lobe, anterior to the trachea and immediately behind the sternum, although about 10% are situated posterior to the trachea and oesophagus. The histological features are no different from those of a cervical goitre and they are usually non-toxic.

### *Clinical features*

Retrosternal goitre occurs more commonly in females and in the middle-aged and elderly [277]. An Australian epidemiological study carried out during a mass radiography campaign found the incidence to be 1 in 2000 in females over the age of 45 years compared with 1 in 5000 for the whole of the population that was screened [280]. When symptoms occur, they usually come on insidiously as growth is generally slow. Dyspnoea is the most common symptom and may be accompanied by cough and stridor due to tracheal compression. Other symptoms are less frequently encountered and include dysphagia, hoarseness due to recurrent laryngeal nerve palsy and,

occasionally, those of thyrotoxicosis. Obstruction of the superior vena cava may occur [277]. A goitre is usually palpable in the neck but this sign may be easily missed in an obese patient. A retrosternal extension should always be suspected in a breathless patient with a cervical goitre or a thyroidectomy scar. Patients with ectopic thyroid tissue in the absence of a goitre in the neck are usually free of symptoms, the diagnosis being made at thoracotomy following the finding of an anterior mediastinal mass shadow on a routine chest radiograph taken for some other purpose.

Intrathoracic goitres may be complicated by haemorrhage into the substance of the gland, which can produce sudden severe dyspnoea that constitutes a surgical emergency. Malignant change was found in 16% of one surgical series of retrosternal goitres and is no less likely if the goitre is long-standing [277].

### *Investigation and diagnosis*

Posteroanterior and lateral chest radiographs show a rounded opacity occupying the anterior and superior mediastinal compartments. The upper border is usually indefinable because of extension into the neck. The shadow is often more prominent on the right and may displace the trachea (Fig. 49.13). Calcification is occasionally visible.

A positive radioactive iodine isotope scan is diagnostic of the presence of functioning thyroid tissue in the neck and mediastinum and is found in over half of all cases of retrosternal goitre. However, a negative scan does not exclude goitre since the thyroid tissue may be non-functioning [281]. Technetium-99m is sometimes used but

**Fig. 49.13** Retrosternal goitre showing marked displacement of trachea to the right.

although more convenient is less reliable, occasionally giving negative results where iodine-131 uptake is positive.

CT is capable of demonstrating the anatomical continuity of a retrosternal goitre with the lower pole of cervical thyroid; where there is no such continuity, the presence of ectopic thyroid may be suspected [282]. The iodine content of thyroid tissue may give higher attenuation values than would be expected from a soft tissue mass of non-thyroid origin. A barium swallow may be carried out when dysphagia is present and thyroid function is assessed biochemically.

The differential diagnosis includes any superior or anterior mediastinal tumour, particularly thymic masses and germ-cell tumours. Sometimes an aortic aneurysm may be suspected, in which case MRI, CT with contrast or aortography may be used.

### *Treatment*

It is a general rule that intrathoracic goitres should be surgically removed provided that the patient is fit enough to undergo the operation. The reasons for this are obvious in a symptomatic patient, although removal is still justified in symptom-free subjects in order to avoid the development of rare potentially life-threatening complications, such as haemorrhage into the substance of the gland [277]. The vast majority of thoracic extensions are removed using a cervical approach. Where an anterior mediastinal component is very large, the collar incision may need to be extended by a sternotomy [4].

### **Parathyroid adenomas and cysts**

Mediastinal parathyroid adenomas are sometimes found when surgical exploration of the neck in a patient with hyperparathyroidism fails to reveal a tumour in the usual location. The occasional ectopic position of these adenomas is explicable in terms of the common embryological development of the inferior parathyroid gland and the thymus, both of which arise from the third branchial pouch, so that ectopic parathyroid lesions may be found embedded in the thymus gland. One series found 7% of parathyroid adenomas to be situated in the mediastinum [283]. In another series of 400 patients with hyperparathyroidism, 21% had mediastinal adenomas [284]. The majority of these could be removed via a cervical incision and only 19 required a sternotomy. About 65% of mediastinal parathyroid adenomas are situated in the anterior part of the superior mediastinum and the remainder in the posterior part [285]. They often go unnoticed preoperatively because they are often small and nodular, although they may grow larger than their counterparts in the neck without exciting attention. Attempts may be made to identify small tumours by CT, MRI, radioisotope scintigraphy,

selective arteriography and venous sampling with parathormone assay [286–289]. Hormonally inactive mediastinal parathyroid cysts occasionally occur and may be large enough to manifest themselves on plain chest radiographs [290]. They have been known to cause symptoms of tracheal compression and recurrent laryngeal nerve palsy [291].

### **Aortic aneurysm**

Aortic aneurysms enter the differential diagnosis when a widened mediastinum is found on the chest radiograph. They have been defined as a permanent localized dilatation of the aorta that results in a diameter at least 50% greater than normal [292]. The possible causes range from degenerative change associated with cystic medial degeneration and atherosclerosis, to congenital disorders such as Marfan's syndrome and Ehlers–Danlos syndrome to connective tissue disorders, trauma and infection [293]; the most important single risk factor for dissection is hypertension.

### *Clinical features*

Frequently, thoracic aortic aneurysms are asymptomatic at the time of detection. However, pressure on adjacent structures may occur during the course of enlargement, with dysphagia, stridor or dysphonia due to compression of the oesophagus, trachea and left recurrent laryngeal nerve. Compression of the superior vena cava may also occur. Aneurysms of the aortic arch may cause pain referred to the neck and jaw, and those involving the descending thoracic aorta may cause interscapular or left chest pain. The sudden onset of such pain may indicate an acute aortic dissection or intramural bleed [293]. Other symptoms may result from heart failure in connection with associated aortic regurgitation or may be the result of the occlusion of aortic branches. Aneurysms of the brachiocephalic (innominate) and left common carotid arteries may also produce superior mediastinal 'mass lesions' on the chest radiograph and symptoms of tracheal compression [294].

### *Investigation*

Although often first suspected following chest radiography, plain chest films may miss significant retrosternal aneurysmal dilatation and cannot always differentiate a vascular opacity from other mediastinal masses [295]; indeed thoracic aortic aneurysms have sometimes been unwittingly subjected to percutaneous needle biopsy with alarming results for all concerned. MRI provides the best images of thoracic aortic disease, particularly dissections, and does not require contrast; however, it is difficult to perform on iller patients who may be attached to

monitoring devices and CT is still widely used [294] (Fig. 49.14). CT or MRI may be carried out serially in order to monitor the size of aneurysms so that decisions can be made about when to intervene surgically, although aortography is still usually required before elective surgical intervention.

### *Treatment*

Surgical treatment is intended to reduce complications and in particular to prevent death from rupture. Series of patients with thoracic aortic aneurysms who did not undergo surgery showed that rupture of the aneurysm

(a)

(b)

**Fig. 49.14** (a) Chest radiograph showing a large suprahilar mass, which CT contrast imaging (b) showed to be a hugely dilated aneurysmal aortic arch containing mural thrombus in its lateral aspect.

was the most common cause of death, rates ranging from 42 to 70% [293,296]. The risk of rupture is increased for dissecting aneurysms and is also much greater for aneurysms exceeding 6 cm in diameter [296]. The earliest successful cardiothoracic surgical replacements of the ascending aorta and aortic arch were carried out over 40 years ago, since when there have been considerable improvements in both surgical and cardiopulmonary bypass techniques. At present, in asymptomatic patients consideration is given to replacing thoracic aortic aneurysms with grafts when the diameter of the aneurysm exceeds 5–6 cm, although these figures may well be reviewed as experience accrues. All patients with acute dissections of the ascending aorta should be considered for surgery, without which about 90% die within 3 months. A mechanical aortic valve prosthesis may be incorporated into the ascending aortic graft if this is necessary and the coronary arteries are implanted into the graft. The aortic arch may also be replaced with a graft where necessary and this may be indicated in acute dissection where an intimal tear has occurred in the arch. Most acute aortic dissections affecting the descending aorta may be managed medically at first, blood pressure being controlled with drugs such as nitroprusside.

## Diaphragmatic herniae

Hiatus herniae are a common cause of a double retrocardiac 'shadow' that often contains a fluid level, the lateral radiographic projection confirming the physician's suspicion. These are often incidental findings on a radiograph taken for some other reason and patients with surprisingly large hiatus herniae may have no symptoms referable to them, in which case surgical intervention is seldom justified. Symptoms of oesophageal reflux may occur and can usually be dealt with medically. There is a small risk of paraoesophageal herniae becoming incarcerated and strangulating and when this does happen it creates an acute surgical emergency. Surgical intervention may also be needed to dilate oesophageal strictures should these arise. Diaphragmatic herniae may also occur posteriorly through the foramen of Bochdalek or anteriorly through the foramen of Morgagni. Bowel or omentum or both may be contained in the hernial sac. These and other diaphragmatic lesions that may sometimes abut the mediastinum are described more fully in Chapter 46.

## Mediastinitis

### Acute mediastinitis

#### Causes

The commonest cause of acute mediastinitis is oesophageal perforation [297]. This may occur as the result of a difficult endoscopy. Attempts to dilate a stric-

ture or to insert a tube or stent for palliative purposes in carcinoma may have the same effect and a carcinoma may itself perforate spontaneously. Other causes of oesophageal perforation include accidental blunt or penetrating injury of the chest, surgery to the oesophagus or adjacent structures and ingestion of a foreign body. Forceful vomiting commonly causes a Mallory–Weiss mucosal tear but it is unusual for the entire wall of the oesophagus to rupture (Boerhaave's syndrome).

Infection may also track down to the mediastinum from higher levels, particularly along the so-called 'danger space', a potential cavity created by a fascial plane that runs from the upper cervical level as far caudally as the diaphragm [298]. Infection from the mouth, neck or retropharyngeal space may extend into this space, between the prevertebral fascia posteriorly and the alar fascia anteriorly, and result in acute mediastinitis. The portal of entry is occasionally a small oropharyngeal mucosal tear resulting from a difficult endotracheal intubation. Other less common causes include the extension of infection from the lung, pleural or pericardial cavities, with or without abscess formation. The spread of such infection may be direct or it may be carried by lymphatic drainage, with subsequent suppuration of mediastinal nodes. Osteomyelitis of the cervical or dorsal spine, ribs or sternum may also spread directly to the mediastinum. Surgical incisions in the neck and thorax may become infected with subsequent mediastinitis, particularly following tracheostomy and sternotomy. Infection may also reach the mediastinum from central venous cannulation sites in the neck. Tuberculous mediastinitis is now rare as is haematogenous spread of infection from remote sites.

### Clinical features

The patient usually feels ill and is febrile. There may be rigors. Swallowing often produces pain so that food is refused. Movements of the neck may produce discomfort if infection has tracked down from this area, so that the anxious patient may look fixedly to the front. A cough may indicate tracheal involvement. Mediastinal and subcutaneous emphysema may occur, particularly if the oesophagus is perforated, and a pleural effusion, empyema or pyopneumothorax may sometimes be produced. Retrosternal pain may be present and sternal tenderness may be elicited.

### Investigation

The chest radiograph may be normal or if fluid or pus are collecting in the mediastinum, a smooth-walled convex opacity may be seen bulging laterally beyond the mediastinal boundaries with displacement of the trachea and oesophagus (Fig. 49.15). Gas may be seen in the

(a)

(b)

**Fig. 49.15** (a) Posteroanterior film of patient with mediastinal abscess following faulty placement of central venous canula showing mass to right of upper mediastinum. (b) Right lateral view showing opacity surrounding trachea and displacing it forwards.

mediastinum or fascial planes of the neck, this being a feature of a mixed anaerobic infection in which organisms have gained entry from the oropharynx. There may be evidence of a pleural effusion or pyopneumothorax. Lateral soft tissue radiographs of the neck may show an increase in width of the retropharyngeal soft tissue. CT may show retropharyngeal inflammatory changes and gas, with possible extension to the mediastinum. This examination should be performed early as it may well show abnormalities at a time when plain radiographs are normal or show only subtle changes. The presence of a mediastinal abscess may also be shown by CT. Leakage through an oesophageal or pharyngeal tear may sometimes be demonstrated if a water-soluble non-ionic contrast (e.g. lopamidol, Gastromiro) examination of the oesophagus is undertaken. High-osmolality contrast media such as Gastrografin tend to be avoided as any 'spillover' into the lung in the presence of dysphagia may result in pulmonary oedema.

### **Treatment**

The patient should be monitored closely as acute mediastinitis is potentially fatal. Treatment consists of a broad spectrum of parenteral antibiotics, including cover for anaerobic bacteria [299]. Initial combinations might include penicillin and metronidazole plus an aminoglycoside, or clindamycin also with an aminoglycoside. Surgical drainage is essential where there is radiographic evidence of an accumulation of pus in the neck and/or mediastinum, in which case early thoracic and otorhinolaryngological opinions are necessary. Both these territories may require separate drainage and a thoracotomy may be required to achieve adequate mediastinal drainage [298]. Any pleural collections that may be present also require adequate drainage. The degree of intervention depends upon the nature and extent of the underlying disease process, so that a foreign body may be removed endoscopically, a postmetic oesophageal rupture repaired, and an advanced and inoperable oesophageal carcinoma managed conservatively. A literature review of necrotizing mediastinitis found a mortality rate of 31%, despite the availability of antibiotics [298].

### **Chronic mediastinitis**

Chronic mediastinitis may be caused by low-grade infection and in such cases the responsible organisms may be fungal or mycobacterial. It is possible that John Hunter's mid-eighteenth century description of mediastinal fibrosis (see below) may have been caused by tuberculosis or even syphilis [300]. More recent series from North America have implicated *Histoplasma capsulatum*, this organism having been found to be responsible for 26 cases of mediastinal granuloma or fibrosis in the series of Goodwin, the

remaining 12 cases being thought to have been caused by *Mycobacterium tuberculosis* [301]. The condition may also sometimes occur with nocardiosis [302], actinomycosis [303], blastomycosis [304], coccidioidomycosis [304] and aspergillosis [305]. Patients may be asymptomatic, coming to attention following the finding of mediastinal widening on a chest radiograph taken for some unrelated reason. They may also present with symptoms of cryptogenic mediastinal fibrosis, into which chronic mediastinitis imperceptibly merges. Where an infecting agent is identified, appropriate antimicrobial therapy can be tried but usually fibrotic change predominates so that any therapeutic distinction from cryptogenic mediastinal fibrosis is problematical. Antifungal agents have been tried when histoplasmosis was suspected as the cause but evidence of benefit is somewhat anecdotal and no controlled trials have been carried out [306].

### **Cryptogenic mediastinal fibrosis**

The different names that have been attached to this condition are a reflection of both its rarity and a general sense of ignorance about its cause. These names include fibrosing mediastinitis, sclerosing mediastinitis, chronic fibrous mediastinitis, chronic mediastinal fibrosis and idiopathic fibrosis of the mediastinum. All these terms are intended to convey the slowly progressive envelopment of mediastinal structures in fibrotic tissue.

### **Possible causes**

The first description has been attributed to John Hunter in 1757 [300]. Although such early reports may well have included cases due to tuberculosis or even syphilis, which were highly prevalent at the time, more recent descriptions have failed to identify a cause in over 80% of cases, hence the use of the term 'cryptogenic'. Those few cases where the aetiology is known should be referred to as chronic mediastinitis or mediastinal fibrosis due to whatever causal agent has been identified (as above). Infection with *H. capsulatum* is a recurrent theme in North American reports of fibrosing mediastinitis [307,308]. This infection is highly endemic in parts of the central USA, where residence produces almost invariable infection that is of no clinical consequence in the vast majority [309]. It has been proposed that immune stimulation may result from the seepage of material from infected lymph nodes; however, cultures and silver stains are usually negative in these cases and although there is a strong suspicion of an association between *Histoplasma* infection and consequent mediastinal fibrosis, clear proof is often lacking. It has also been suggested that the mediastinal fibrosis in these cases results from a delayed hypersensitivity reaction to mycobacterial, fungal or other unidentified antigens [301]. It is notable that histological reports where histoplasmosis

is the supposed cause refer to the presence of granuloma formation and caseation, hence the term 'mediastinal granuloma', whereas these are not regarded as typical features in European reports of the cryptogenic form [310,311].

A retrospective series of 18 patients collected at one British centre over the space of 23 years obtained a history of previous pulmonary tuberculosis in half of them but with no evidence of active infection at the time of diagnosis [311]. Cryptogenic fibrosing mediastinitis is occasionally associated with retroperitoneal fibrosis and both these conditions may sometimes coexist with Riedel's thyroiditis, sclerosing cholangitis, orbital pseudotumour and sclerosing mesenteritis. The histological similarities between all these conditions have been noted and have given rise to the term 'multifocal fibrosclerosis', which implies a systemic disorder with a possible common aetiology [310]. There have been reports of hypergammaglobulinaemia and hypercomplementaemia, as well as a prominent plasma cell infiltration, in patients with cryptogenic fibrosing mediastinitis and this has stimulated speculation that there may be an immune basis for the disorder [312]. Practolol and methysergide have been associated with peritoneal and retroperitoneal fibrosis. The former, a  $\beta$ -blocker, has been withdrawn from use and neither of these drugs, the second of which is used as prophylactic treatment for severe migraine, has been shown to cause mediastinal fibrosis, although pleural effusions, pleural friction rubs and microscopic evidence of pulmonary fibrosis have been described in a few patients receiving methysergide therapy [313].

### *Pathology*

Masses of ill-defined sclerotic tissue encase and may compress the mediastinal structures. Any part of the mediastinum may be involved and tissue planes are not respected. Histology shows that the predominant feature is the presence of bundles of intertwining hypocellular collagenous tissue containing an infiltrate of mainly plasma cells with some lymphocytes, polymorphs and fibroblasts, the process extending into surrounding connective tissue and fat [310,312].

### *Clinical features*

The diagnosis is most commonly made in the fourth decade of life, although the condition may occur at any age. It is found with equal frequency in men and women. It may be identified following the finding of mediastinal widening on the chest radiograph of an asymptomatic individual or it may present with the insidious onset of symptoms of obstruction of the superior vena cava, so that the patient may notice swelling of the face, neck and arms, particularly in the mornings, at which time there may be

headache and difficulty in buttoning the shirt collar [314]. Conjunctival oedema and anterior chest wall and neck vein engorgement may become evident and the patient may have a suffused complexion. These symptoms do not inevitably progress, presumably due to either the cessation of the fibrotic process or the opening up of collateral vessels [304]. Other symptoms may include dyspnoea and dysphagia, since both tracheobronchial and oesophageal compression may occur.

In some cases the fibrotic process may be limited to one or both hilar regions, with possible narrowing of the hilar vasculature and bronchi [315]. Bronchial compression may cause cough, breathlessness and recurrent lower respiratory tract infection. Pulmonary arterial hypertension may be produced if compression is bilateral. Haemoptysis may be produced by infection, bronchial invasion or as a result of pulmonary venous hypertension. It has been suggested that this distribution of fibrosis is more likely to be found in younger age groups but this may be an oversimplification [315,316].

### *Radiographic features*

These are non-specific. There may be widening of the mediastinal shadow and the mediastinum may be displaced towards the side of the most dense fibrosis. Either hilar shadow may be prominent. Calcification within the fibrotic mass may sometimes be seen. An affected pulmonary artery may be small. There may be cardiomegaly and compressed pulmonary veins may produce Kerley's B lines. A barium swallow or bronchoscopy may demonstrate areas of compression or distortion. There may be confusion with chronic thrombotic pulmonary arterial occlusion in those cases with pulmonary arterial hypertension, and this may be compounded by similar appearances on ventilation-perfusion lung scanning and pulmonary arteriography [317]. CT and MRI of the mediastinum may help to delineate the extent of the disease process [318,319], although biopsy is necessary to provide a tissue diagnosis and to exclude a neoplastic process, particularly as a fibrotic reaction may be associated with some tumours including lymphoma. This is best done surgically, usually by mediastinoscopy or anterior mediastinotomy provided that the patient is fit enough, and several blocks of tissue should be obtained. It is important that the diagnosis is confirmed histologically, since in the days before CT 'blind treatment' with radiotherapy on the assumption that a carcinoma was responsible for obstruction of the superior vena cava has been known to produce a later myelopathy with a tragic and permanent neurological deficit.

### *Treatment*

Medical treatment has nothing to offer, corticosteroids

having proved ineffectual and penicillamine having been of no demonstrable benefit [320]. Occasionally, fibrotic tissue may be localized and is surgically removable but usually it is diffuse and cannot be cleared. A bypass graft may relieve obstruction of the superior vena cava in severe

cases that do not develop an adequate collateral drainage [311,321]. Oesophageal strictures may require dilatation. Attempts to dilate bronchial strictures have been known to cause severe bleeding.

# DEVELOPMENTAL DISORDERS OF THE LUNGS

DOUGLAS SEATON AND ANTHONY SEATON

Developmental disorders of the lungs are for the most part congenital, i.e. they exist from birth, being the consequence of disordered organogenesis following conception. As the development of the respiratory tract occurs according to a strict timetable (see Chapter 1), abnormalities present at birth may be accurately dated to disturbances of intercellular relationships that have occurred at fixed points in intrauterine life. Although major structural abnormalities of the respiratory tract and its adnexae are usually fatal, such effects are now frequently diagnosed before birth or early in postnatal life so that corrective surgery may be applied in certain cases. Other developmental anomalies may not manifest themselves until much later in life and although rare are of considerable interest to the practising physician.

A number of genetically based and ultrastructural disorders, including ciliary abnormalities, cystic fibrosis,  $\alpha_1$ -antitrypsin deficiency and skeletal dysplastic syndromes or chondrodystrophies, are considered elsewhere in this book. Hamartomas of the lung (mesenchymomas) are considered as benign neoplasms in Chapter 42.

## Tracheobronchial anomalies

The lower respiratory tract shares its embryological origin with the primitive foregut, arising from its ventral surface in the fourth week of intrauterine life as an epithelial laryngotracheal bud or 'respiratory primordial pouch' [1–3]. The subsequent development of the tracheobronchial tree and oesophagus proceeds concurrently, with the result that congenital abnormalities of one frequently involve the other, over 50 such anomalies having been recorded [4]. Respiratory tissues comprising airways and spaces distal to the terminal bronchioles are derived from mesoderm and are developmentally connected to epithelially derived proximal conducting airways in order to form a normal gas-exchanging pathway. Developmental errors of the tracheobronchial tree cannot arise after the 16th week of intrauterine life, since by this time its formation is complete [5].

## Tracheal agenesis

Tracheal agenesis or aplasia refers to the absence of growth in the trachea or in part of it. It has a male to female preponderance of 2:1 and is often incompatible with life [6,7]. Three main anatomical patterns are recognized [8].

Type 1, in which there is agenesis of the proximal trachea, accounts for 20% of cases. The distal trachea is present and is often connected to the oesophagus by a fistulous communication.

Type 2, in which the main bronchi join in the midline and communicate with the oesophagus by a single fistula, is the most common variety accounting for 60% of cases.

Type 3, in which the left and right main bronchi join the oesophagus independently, accounts for the remaining 20% of cases.

Occasionally, the coexistence of a tracheo-oesophageal fistula permits air to enter the lungs so that the infant may survive for a period. In these circumstances, early diagnosis may allow temporary measures to sustain respiration and later reconstructive surgery to be undertaken [9–11].

Sometimes the trachea, though patent, is shortened owing to the absence of a number of cartilaginous rings, as in congenital brevicollis or the 'short neck syndrome', most commonly associated with Klippel–Feil syndrome, and characterized by a triad of short neck, decreased neck mobility and low occipital hairline [8,12].

## Tracheo-oesophageal fistula

The H-type tracheo-oesophageal fistula (Fig. 50.1), in which both the trachea and oesophagus remain patent, may be sufficiently small to go undetected until adult life, despite the presence of recurrent symptoms from infancy [13,14]. Aspiration of oesophageal contents into the airways may cause choking, with cough and cyanotic episodes after feeding. The passage of air through the fistula and into the oesophagus in the reverse direction

Fig. 50.1 H-type tracheo-oesophageal fistula.

may cause abdominal distension. Recurrent pneumonia is common [15]. Tracheo-oesophageal fistula may occur in partial tracheal agenesis [8] and also in oesophageal atresia, typified by a blind proximal pouch and distal fistulous communication between the lower oesophagus and trachea [16]. Tracheo-oesophageal fistula may also occur familiarly [17].

### Tracheal stenosis

Tracheal stenosis (Fig. 50.2) is diffuse in 30% of cases, the pars membranacea being absent so that the trachea is encircled by 'napkin-ring' cartilages, the total number of which may exceed the usual complement of 22. More commonly (50% of cases) the stenoses are segmental and may occur with equal frequency in the upper, middle and lower parts of the trachea. In 20% of cases the stenosis is carrot or funnel-like and this is associated with the 'sling' left pulmonary artery syndrome, described below [18,19]. Tracheal stenoses are associated with tracheo-oesophageal fistulae, and accessory bronchi arising from the trachea may also be found [20]. An association with Down's syndrome has been reported [21]. The condition usually presents in infancy with stridor and respiratory insufficiency. Surgical treatment may be necessary, and various plastic tracheal reconstruction procedures have been described [22–24].

### Tracheal narrowing due to extrinsic pressure

Congenital tracheal narrowing due to extrinsic pressure generally results from the close proximity of unusually large or abnormally placed vessels that have arisen as the

Fig. 50.2 Three types of tracheal stenosis.

result of faulty development of the primitive system of branchial arches (see Chapter 1). These anomalies are, in order of frequency, double aortic arch (47%), right aortic arch with left ligamentum arteriosum (20%), retro-oesophageal right subclavian artery (14%), anomalous innominate artery (11%), anomalous left carotid artery (4%), retrotracheal or 'sling' left pulmonary artery (3%) and right aortic arch with aberrant left subclavian artery (1%) [8,25]. Occasionally, the combination of anomalous vessels with congenital tracheal stenosis requires surgical repair [26].

### Tracheomalacia

This term is used to indicate excessive weakness and collapsibility of the tracheal walls as a result of abnormally soft or pliable cartilages. It may occur in localized form as the result of a deficiency of cartilage in a short segment of trachea [27]. This condition may be mistakenly diagnosed in the presence of obstructive airways disease in which high intrathoracic pressures are produced during expiration, with resultant compression of even the normal upper respiratory tract. It should be noted that acquired forms of tracheomalacia occur as a result of prolonged endotracheal intubation and in the rare systemic disorder of cartilage known as relapsing polychondritis (see Chapter 45). Tracheomalacia may be associated with other tracheo-oesophageal anomalies and presents in childhood with expiratory airflow obstruction and apnoeic episodes. In severe cases surgical intervention with aortopexy and various tracheal splinting procedures may be necessary [28,29].

### Tracheobronchomegaly

Tracheobronchomegaly [30–33] is a rare disease character-

ized by unusual width of the trachea and main bronchi and, because of the ineffectiveness of cough, often complicated by lower respiratory infection and bronchiectasis [34]. The cough may have a loud booming quality. The disease is probably congenital and may be inherited as an autosomal recessive; it has been recorded in association with Ehlers–Danlos syndrome. Most reported cases have been in young adults but it has been found in children. There is an atrophic or congenital defect of the connective tissues of the trachea and main bronchi. The condition may be missed on the plain chest film but is obvious on the tracheo-bronchogram and on CT or magnetic resonance imaging [35]. There is gross variation in diameter of the trachea with respiration and there may be other distortions and irregularities.

Those of the foregoing conditions that cause either a structural or functional narrowing of the trachea may produce clinical features, including wheezy dyspnoea, respiratory distress during feeding, recurrent lower respiratory tract infection, stridor, tugging inspiratory effort with intercostal muscle retraction, cyanosis and apnoeic episodes.

#### **Abnormal patterns of bronchial branching**

These are usually found at bronchoscopy and are seldom

of clinical significance, other than when resective surgery is being undertaken for some other reason. The abnormalities are more often additive than subtractive and, as might be anticipated, more variability is found at segmental level than in larger proximal bronchi. The most common major anomaly is a supernumerary right upper lobe bronchus [36], which may arise anywhere from the trachea or right main bronchus (Fig. 50.3). The frequency of tracheal origin is estimated at 0.9% and of double origin from the right upper lobe bronchus at 0.4% [37]. Sometimes the origin of an upper lobe bronchus may be displaced so that it arises only from the trachea with no separate main bronchial origin. Absence of an upper lobe bronchus is the most common of the major subtractive abnormalities (0.3%). The most common segmental anomaly is a double-stem apical lower lobe segmental bronchus that occurred in 7% of one series [37], the incidence being slightly higher on the right than on the left. Unusually, an apical upper lobe segmental bronchus may arise from the trachea in either displaced or supernumerary fashion.

Bronchial isomerism is a term applied to a rare group of developmentally anomalous syndromes in which the normal pattern of bronchial branching in either the left or the right lung is mirrored in the contralateral lung, resulting in a so-called bilateral left or right lung. Developmen-

**Fig. 50.3** Supernumerary right upper lobe bronchus arising from trachea shown at bronchography.

tal abnormalities of the heart, great vessels, liver, spleen and gut frequently coexist [38].

### **Bronchial atresia**

This rare condition has been reviewed by Meng and colleagues [39]. It probably arises as a result of a developmental interruption of normal bronchial continuity in which a length of bronchus, usually the apicoposterior segmental bronchus of the left upper lobe [40], becomes sealed off from the larger proximal airways to which it may remain connected by thin, uncanalized, fibrous, vestigial strands. This sealed-off or atretic bronchus becomes distended by bronchial secretions, resulting in the formation of a cystic space or mucocoele. Some degree of collateral ventilation to lung subtended by the atresia is maintained via the inter-alveolar pores of Kohn, although normal postnatal alveolar development to this part of the lung is retarded, with a reduced alveolar count. The pattern of bronchial branching distal to the atretic segment, having developed antenatally, remains intact [41]. Abnormalities of the vascular supply of the affected lungs have been recorded and may be causally related to bronchial atresia, as may a described association with pectus excavatum [42].

The majority of patients are asymptomatic and the diagnosis of bronchial atresia is made in young adult life following a chest radiograph that has been requested for some other reason. Less than one-third of patients present with symptoms due to lower respiratory tract infection. The chest radiograph shows the mucocoele as a coin lesion and part of the lung distal to it appears hyperlucent as a result of collateral air trapping. Bronchography showed non-filling of the affected bronchus, and the surrounding bronchi may appear to be displaced by the peripheral zone of hyperlucency [5]. CT allows the diagnosis to be made with some confidence [43]. Although the risk of infection in untreated bronchial atresia is estimated to be low, in most reported cases the diagnosis has been made following surgical excision of the atretic segment by lobectomy or segmentectomy [39].

### **Bronchogenic cysts (syn. bronchial cysts)**

Bronchogenic cysts arise as a result of abnormal budding of the tracheobronchial tree during the course of its development between the 26th day and 16th week of intrauterine life [1,44], in which a tracheal or bronchial bud becomes detached from its parent, thereafter developing separately to produce a cystic structure. Bronchogenic cysts are more common in males and apparently in Yemenite Jews [45,46]. They may be classified according to their situation as either central (syn. mediastinal) or peripheral (syn. intraparenchymal, intralobar). Central bronchogenic cysts presumably arise earlier in the devel-

opmental process, detaching themselves from major airways and occupying a position alongside the trachea, at the level of the carina or close to a main or lobar bronchus, or juxtaposed to the oesophagus [47,48]. If the developmental anomaly arises at a later stage, then the cyst or cysts are situated towards the periphery of the lung. In several reported series the peripheral situation is at least as common as the central one [49–52], and two-thirds of peripheral cysts occur in the lower lobes [36,52]. Bronchogenic cysts are usually single but are occasionally multiple and may sometimes arise in both lungs [36,52]; unusually they may occur in ectopic situations in relation to the pericardium [53], diaphragm [54], vertebral column [55] and skin [56].

### **Pathological features**

Bronchogenic cysts vary in size and may reach 10 cm in diameter [48,52]. Their walls may be thin but increase in thickness following infection. They are usually lined by ciliated respiratory epithelium and contain smooth muscle, elastic tissue, cartilaginous trabeculations and mucous glands. The presence of cartilage in their walls serves to distinguish them from cysts of different origin. A fistulous communication with an adjacent airway may be present, and in these circumstances the cyst may be filled with air. A ball-valve mechanism may cause it to enlarge and present in infancy or exceedingly rarely in young adult life by causing displacement of normal lung [57]. Intact and uninfected cysts contain clear fluid. The presence of infection tends to destroy the characteristic histological features so that it may become extremely difficult to distinguish between a chronically infected bronchogenic cyst and an acquired lung abscess [58]. Complication by development of rhabdomyosarcoma has been described [59].

### **Clinical features**

Bronchogenic cysts are frequently asymptomatic and may come to light as an abnormal shadow on a chest radiograph that has been requested for some unrelated reason. When symptoms do occur, they result from either a mass effect on adjacent structures or more frequently infection. Pressure on the trachea or a proximal bronchus may produce dyspnoea, cough and stridor, and on the heart may cause dysrhythmias. Oesophageal compression may result in dysphagia. Repeated lower respiratory tract infection or atelectasis may be caused by bronchial compression. Should the contents of the cyst become infected, it may enlarge and rupture into either the mediastinum or an adjacent airway, resulting in a cough productive of mucopurulent material or haemoptysis.

### Radiographic features

The diagnosis is suspected following the radiographic finding of a well-circumscribed, rounded, homogeneous opacity situated either in the mediastinum close to a major airway or in the lung periphery (Fig. 50.4). If a fistulous communication is present, an air–fluid level may be visible and rarely it may mimic a large emphysematous bulla. The presence of calcification in the wall of the cyst is a variable and uncertain feature. If the cyst is centrally situated, a barium swallow may demonstrate oesophageal compression.

### Treatment

Elective surgical resection of the lesion is generally advised because it is often impossible to make a firm diagnosis preoperatively, and a neoplastic condition cannot be excluded with certainty. Furthermore, there is a tendency for bronchogenic cysts to undergo serious or even lethal complications [60–62]. Only with small asymptomatic cysts or in patients in whom surgery is contraindicated is there a case for their being left *in situ*, and then only after needle aspiration [63].

### Congenital adenomatoid malformation of the lung

This condition is synonymous with congenital cystic adenomatoid malformation of the lung and in older literature was probably called congenital bronchiectasis or pulmonary cystic disease [8]. It may involve either a part or the whole of a lobe or rarely an entire lung. The affected lobe or lung derives its blood supply from the pulmonary circulation and comprises a firm and airless mass of disorganized pulmonary tissue that lacks a properly defined bronchial system but contains an excess of air passages resembling terminal bronchioles and often includes mucous cysts of varying sizes [64]. Occasionally, the congenital adenomatoid malformation may consist of a separate mass connected by an extra bronchus to the normal bronchial tree, in which case it can be regarded as a form of accessory lung. Stocker and colleagues [65] described 38 cases that they classified into three types.

Type I, characterized by single or multiple large cysts, was the most common form, accounting for 50% and carrying a good prognosis.

Type II, consisting of multiple small cysts of less than 1 cm in diameter, accounted for 40% of cases and carried a poor prognosis.

Type III carried a very poor prognosis and consisted of a solid airless mass of tissue.

It has been suggested that adenomatoid malformation of the lung results from a developmental failure of the

proximal bronchial system, arising from the epithelial laryngotracheal bud, to unite in a normal manner with mesodermally derived distal alveolated tissue [58]. To this extent it may be regarded as a developmental anomaly of both the tracheobronchial tree and the lung parenchyma.

About 50% of cases are born prematurely and 25% are stillborn [8]. Many of those born alive die within a few hours, often with anasarca caused by vena caval compression due to the space-occupying effect of the abnormal tissue mass. Infection of the cysts commonly occurs if the infant survives beyond the neonatal period, although the onset of symptoms may be delayed for 2 or 3 years [66]. The condition may be complicated by pneumothorax that occurs as a result of air trapping in the cystic spaces [67]. The condition may now be diagnosed antenatally by ultrasound examination, and in some cases treatment by surgical resection of the affected parts of the lung is practicable [68].

### Anomalies involving the lung parenchyma

#### Agenesis and hypoplasia of the lung

Inconsistencies in the use of the terms ‘agenesis’ and ‘hypoplasia’ may be found in the literature [8,36]. In this book the term ‘agenesis’ is taken to mean absence or almost complete absence of growth in the lung [58], while the term ‘hypoplasia’ indicates underdevelopment but not non-development of the lung. Thus the hypoplastic lung contains a normal number of lobes but is diminished in size, with fewer bronchial branchings and reduced numbers of alveoli.

Complete bilateral agenesis of the lungs is extremely rare [69]. Needless to say, it is incompatible with life. Unilateral agenesis of the lung is much less rare and may be present to varying degrees of severity [8,70]. The left lung is affected more frequently than the right and the majority of cases exhibit other congenital abnormalities, one of the most common being patent ductus arteriosus [71–73]. In the most common form of unilateral agenesis there is a rudimentary bronchus but complete absence of lung tissue. In a second form there is a total absence of both the lung and bronchial system, and in a third, the least common, there is a rudimentary bronchial system attached to a reduced amount of alveolated tissue, this form being more properly regarded as an example of lung hypoplasia.

In many patients the aetiology is unknown. However, conditions that decrease intrathoracic space, especially congenital diaphragmatic herniae, may cause unilateral lung hypoplasia [74–76] and this may also be associated with ipsilateral congenital vascular anomalies [77]. Bilateral pulmonary hypoplasia is associated with the presence

**Fig. 50.4** Posteroanterior (a) and lateral (b) chest radiographs of a 24-year-old man with large right-sided bronchogenic cyst.

of oligohydramnios caused variously by renal tract disorders or by amniotic fluid leak [78,79]. An important cause is premature rupture of the membranes, and impaired lung development is detectable antenatally by ultrasonographic measurement of chest wall diameter [75,80,81]. It has also been shown that maternal treatment with angiotensin-converting enzyme inhibitors during pregnancy may be associated with lung hypoplasia [82].

#### Clinical features and diagnosis

Agenesis or hypoplasia of the lung is frequently associated with major extrapulmonary developmental abnormalities, and when this is the case death frequently occurs in infancy. When the anomaly is confined to a lung or part of it, prolonged survival may be possible but is likely to be accompanied by recurrent episodes of lower respiratory tract infection. This may result from imperfect drainage of lung secretions or from the spillover of pooled secretions from a blind bronchial stump into initially normal lung tissue [83].

The chest radiograph in agenesis or hypoplasia of the lung shows a hemithorax of diminished volume with crowded ribs, elevated hemidiaphragm and mediastinal displacement to the affected side. The contralateral lung tends to overinflate and may expand across

the midline [84] (Fig. 50.5). These appearances resemble atelectasis, and bronchoscopy, CT and occasionally pulmonary angiography may be required to make the distinction.

#### Congenital abnormalities of lobulation

Whereas complete agenesis of a lobe of the lung is rare [85], congenital anomalies of lobulation are much more common and one of those most frequently encountered is the so-called azygos lobe. An azygos lobe is really the medial portion of a bifurcated right upper lobe and in humans may be regarded as an anatomical variation, although students of comparative anatomy are aware that it is said to be a constant feature in the porpoise. It is formed during lung development if the apex of the right lung, as it enlarges, encounters the azygos vein as this vessel arches over the root of the right lung to join the superior vena cava. Whereas in normal circumstances the entire right upper lobe lies lateral to the azygos vein, in the case of this anomaly the right upper lobe assumes a bifid configuration so that a portion of lung lies on either side of the venous arch formed by the azygos vein [86]. The invagination that the azygos vein produces in the right upper lobe is in effect a supernumerary fissure and is bounded on each side by a layer of visceral and parietal pleura (Fig. 50.6). This fissure shows characteristically on chest radiographs as a thin outwardly convex line ending in a small triangular shadow at its lower end (Fig. 50.7).

The bronchial anatomy remains intact and the presence

**Fig. 50.5** (a) Posteroanterior chest film showing a hypoplastic right lung. (b) Tomogram of same patient showing anomalous veins draining a hypoplastic lung.

of an azygos lobe carries no morbidity. It is important only in that its features, which are present in about 0.25% of chest radiographs, require correct interpretation. A similar anomaly may very rarely occur in the left upper lobe [87].

### Lung sequestration

This term covers a spectrum of related developmental pulmonary anomalies generally characterized by the forma-

Fig. 50.6 Pleural infolding of an azygos lobe.

tion of an island of abnormal unventilated lung tissue that has no normal communication with the bronchial system and derives its arterial supply from the systemic rather than the pulmonary circulation.

Two principal types are defined for clinical convenience, namely intralobar and extralobar sequestration [88], although numerous variants have been described and much overlap may occur between these types [58,89]. The abnormal lung tissue in intralobar sequestration, which is the more common of the two types, is contained within the substance of normal lung tissue that completely surrounds it. In the rarer extralobar form the abnormal lung tissue, although lying close to normal lung, is situated outside the pleural coverings of the lung and is indeed invested by its own separate pleural membranes (Fig. 50.8). Since the latter form is entirely disconnected from normal lung, some authors refer to an extralobar sequestration as an 'accessory lung without a bronchial connection' [8,58]. The gender incidence is said to be equal for intralobar sequestration, while the extralobar form occurs four times more commonly in males than females [91]. Both forms occur more commonly in the left hemithorax; however, whereas the intralobar variety occurs on this side in 60% of cases, in the extralobar variety over 90% are left-sided [8,58,71,92]. The reasons for this left-sided propensity are unclear but may be connected with the observation that in normal development the primitive pleuroperitoneal canal closes on the left side later than on the right. Furthermore the absence of hepatic tissue on the left provides additional space in which abnormal tissue may develop. An ipsilateral diaphragmatic defect is

Fig. 50.7 Normal chest film showing typical appearance of an azygos lobe in the right upper zone medially.

common in extralobar sequestration, occurring in 60% of cases, but is rare in intralobar forms [8].

The posterior basal segment of either lower lobe is the most common site for intralobar sequestration. An upper lobe may be involved but this is rare [8,93]. Very occasionally an entire lung may be sequestered [94,95]. The majority of extralobar sequestrations are sandwiched between

the left lower lobe and the diaphragm but may also occur below the diaphragm, within the diaphragmatic substance itself, within the mediastinum or even as far cephalad as the neck [58,96].

The various ways in which sequestered lung may receive its vascular supply have been reviewed by Thilenius and colleagues [97]. Both intralobar and extralobar sequestrations usually receive their arterial supply from the descending aorta or one of its branches, either above or below the diaphragm. Subdiaphragmatic supply is reportedly more common in extralobar sequestration [98], in which case the vessel passes through the aortic or oesophageal hiatus or through a separate diaphragmatic defect. Arteries that supply the intralobar variety tend to be disproportionately large with respect to the volume of tissue supplied [58]; in both the intralobar and extralobar types the supplying arteries may be multiple. The veins draining intralobar sequestrations usually empty into the pulmonary venous circulation, whereas it is more usual for extralobar sequestrations to be drained by the azygos system of veins. Considerable shunts may sometimes result, so that the patient may present in early life with heart failure [99,100].

About half of all patients with extralobar sequestration have other congenital abnormalities of sufficient severity to bring them to medical attention, so that the sequestration is diagnosed in the first year of life in up to 60% of patients. On the other hand, widespread congenital abnormalities in intralobar sequestration are rare [8,58,71] so that the diagnosis is seldom made in neonatal life and, in over 50% of cases, not before the age of 20. Table 50.1 compares some of the features of intralobar and extralobar sequestration.

### Aetiology

Pulmonary sequestration comprises a variety of congenital anomalies for which there is no hereditary basis, and none of the many theories of causation is entirely acceptable unless it has sufficient flexibility to explain the

**Fig. 50.8** Intralobar (a) and extralobar (b) sequestration. (After Gerle *et al.* [90].)

**Table 50.1** Points of comparison between intralobar and extralobar pulmonary sequestration.

Feature	Intralobar	Extralobar
Frequency	More common	Less common
Sex incidence (male : female)	1 : 1	4 : 1
Most common site	Within posterior basal segment	Between lower lobe and diaphragm
Side of thorax	c.60% left	c.90% left
Arterial supply	c.70% thoracic aorta	c.45% thoracic aorta
Venous drainage	Usually pulmonary veins	Often systemic veins
Diagnosed in neonates	Rarely	Commonly
Other congenital defects	Uncommon	Frequent

development of both intralobar and extralobar sequestration as well as more complex variants [58,89,101–103]. Occasional reports of the occurrence of both intralobar and extralobar sequestration in the same patient provide some evidence in support of a unitary theory [104,105]. One such proposition is that pulmonary sequestration develops as a result of the formation of an accessory lung bud distal to the normal laryngotracheal bud on the ventral aspect of the primitive foregut [103]. As this anomalous bronchial tissue grows, it becomes invested by primitive respiratory mesenchyme. The amount of mesenchyme determines the size of the sequestration and results in the development of its respiratory bronchioles and alveolar tissue [106]. The original foregut connection may involute and disappear, possibly as a result of outgrowth of its blood supply, although occasionally a foregut communication persists, particularly in the case of extralobar forms. Those accessory buds that arise in close proximity to the laryngotracheal bud may become incorporated into it during its development to become intralobar sequestrations, whereas those that arise from the foregut more distally either from the oesophagus or from the proximal part of the stomach escape envelopment and become extralobar sequestrations [102]. Each type of sequestration usually retains its primitive systemic arterial supply; venous drainage may be either into the pulmonary system if the sequestration developed in close proximity to the normal laryngotracheal bud, or to the systemic system if it arose more distally [100].

### Pathology

Intralobar pulmonary sequestration appears macroscopically as a well-circumscribed reddish-grey area that may be clearly differentiated from healthy lung but which is intimately related to it, being usually situated within the substance of the posterior basal segment of either lower lobe. An extralobar sequestration is separated from normal lung and the surface is shiny and homogeneous, being covered by its own pleural investment. Both forms typically receive a systemic arterial supply and although this is usually derived from the aorta, the vessels tend to have the elastic structure of a pulmonary artery rather than the muscular structure found in a normal aortic branch. Histologically both intralobar and extralobar sequestrations typically contain dilated ciliated bronchi together with focal development of alveolated tissue. Bronchial dilatation by retained secretions and oedema may result in the formation of cysts visible to the naked eye. The usual histological features may be lost in cases where the sequestration has become infected.

### Clinical features

Those sequestrations diagnosed in the first year of life are

frequently brought to light in the course of the investigation of multiple congenital abnormalities and are usually extralobar in type. Some of those that escape detection in this manner are found in adult life in asymptomatic individuals following a routine chest radiograph. Others may present with non-specific symptoms of lower respiratory tract infection or with recurrent pneumonic episodes, characterized by cough, sputum production and occasionally haemoptysis, which may be massive. These complications may arise because there is a tendency for a sequestered segment to become distended by mucous secretions which, in the absence of a foregut communication, are unable to drain away so that surrounding normal lung tissue becomes compressed and liable to infection. Once infection is established in adjacent lung, a fistula between the sequestered segment and surrounding lung may develop and the infection tends to persist as a result of inadequate drainage.

Extralobar sequestrations may be less liable to infection as they are entirely separate from the normal lung [105]. Signs of pneumonic consolidation may be present but features of pleurisy and pleural effusion are said to be unusual [92]. Finger clubbing has been described, as have associated bony deformities of the ribs and chest wall.

### Radiology and treatment

The radiographic features are variable. The diagnosis of intralobar sequestration should be suspected in the presence of a persistent opacity situated in either of the posterior basal segments (Fig. 50.9). The non-aerated tissue contained in the sequestration may produce a homogeneous shadow, the margins of which are not always well defined but which may have the appearance of a solitary pulmonary nodule. Cystic change may be visible radiographically and the 'cysts' may contain air–fluid levels, implying the presence of either a fistulous bronchial communication resulting from infection or some degree of collateral ventilation occurring at alveolar level (Fig. 50.10). Extralobar sequestration is less easily seen and may produce a small opacity contiguous with the left hemidiaphragmatic shadow. Both types of sequestration occasionally have persistent foregut connections and these are sometimes demonstrable by barium swallow [102,107].

Bronchography showed non-opacification of the sequestration, which was seen to be surrounded by displaced but normally ramifying bronchial branches. The diagnosis is now confirmed by CT and if necessary by retrograde thoracic aortography, which demonstrates one or more feeding arteries that usually arise from the descending aorta just above or below the diaphragm (see Fig. 1.2). These investigations are desirable because by identifying aberrant arteries they exclude other possibilities such as pneumonia, bronchiectasis, lung abscess and tumour, and also forewarn the thoracic surgeon of the existence and

**Fig. 50.9** Sequestered segment in right lower lobe posterior to right cardiac border.

**Fig. 50.10** CT scan of man showing extralobar sequestration posteriorly in the left lung. Note cavitation with fluid level following infection.

distribution of the vessels that require identification and ligation at thoracotomy.

Resection of a symptomatic pulmonary sequestration is indicated. Any infection that might be present is first treated with appropriate antibiotics. Intralobar sequestrations usually require segmental resection or lobectomy

[100]. Extralobar sequestration may be resected without disturbing normal lung. Disastrous bleeding may occur as a result of failure to identify properly the aberrant vascular supply [100] but has also been described as a complication of unresected sequestration [108].

### Anomalies of the pulmonary vasculature

The embryology of the pulmonary vasculature is relevant to the description of the developmental anomalies that follows (see Chapter 1). The intrapulmonary vasculature is derived from the mesenchymal investment of the primitive lung bud. The pulmonary vascular plexus so formed receives its initial arterial supply from paired segmental arteries arising from the aorta. Later the vascular plexus is joined by ramifications of the pulmonary arteries that are themselves derived from the sixth branchial arch. Once this connection is established, and as the aorta migrates caudally, the segmental aortic arteries normally involute and are lost, being replaced by the bronchial arteries that grow out of the aorta at what ultimately will be thoracic level.

The venous side of the pulmonary vascular plexus at first drains into the primitive anterior and posterior cardinal veins, although this route is later replaced when the pulmonary veins from each lung grow out to fuse with a single large pulmonary vein that in turn develops from the sinus venosus. Ultimately this structure is completely absorbed into the atrium to such an extent that the four pulmonary veins normally enter the left atrium separately.

The pulmonary vasculature is well developed by the 16th week of intrauterine life but clearly growth continues *in utero*, as does vascular remodelling at a microscopic level. Disturbances of this remodelling may result in the excessive muscularization of the intra-acinar arteries found in the condition referred to as persistent pulmonary hypertension of the newborn [5,109]. One such case has been described following maternal aspirin ingestion during pregnancy, and it was postulated that pulmonary hypertension in this patient arose as a consequence of premature closure of the ductus arteriosus that had in turn resulted from the prostaglandin-inhibiting effects of this drug [110].

### **Absent pulmonary artery trunk**

The pulmonary artery trunk may be completely absent as a result of agenesis of the primitive sixth branchial arch or of developmental failure of the septum that normally divides the truncus arteriosus into aorta and pulmonary artery trunk. A left-to-right shunt exists in such cases, the lungs being supplied by bronchial or other aberrant systemic vessels; prolonged survival is impossible unless major corrective surgery proves feasible [58,111].

### **Absent unilateral pulmonary artery**

Absence of one or other main pulmonary artery is rare and is a consequence of the failure of either the left or right side of the primitive sixth branchial arch to develop in the embryo. No connection exists between the main pulmonary artery trunk and the lung parenchymal vasculature on the affected side, which receives its blood supply systemically, most frequently from enlarged bronchial vessels but occasionally from aberrant arteries that usually arise from the descending aorta or less frequently from the ascending aorta, the arch, the left innominate artery, the left subclavian artery, their immediate branches or from a persistent right-sided ductus arteriosus.

The left and right pulmonary arteries are affected with equal frequency [112,113] but the right-sided lesion is more common in adult life because absence of the left pulmonary artery is strongly associated with congenital heart disease and therefore with increased early mortality [114]. In one series, 40% of cases of absent left pulmonary artery also had Fallot's tetralogy (ventricular septal defect, pulmonary outflow tract obstruction, overriding aorta and right ventricular hypertrophy) [113]. Absence of the right pulmonary artery carries no strong association with congenital heart disease and hence the tendency for patients with this anomaly to survive. The lung that receives the abnormal blood supply is frequently hypoplastic and may contain cystic and bronchiectatic changes [58]; 20% of patients with a right-sided absent pulmonary artery

have been found to have pulmonary hypertension [115]. Whereas patients who present in infancy usually do so as a result of associated cardiac disease, adults with unilateral absence of a pulmonary artery may be asymptomatic, the diagnosis being made following a chest radiograph requested for some other reason [36]. The affected lung receives its blood supply from systemic vessels and occasionally patients present with haemoptysis. The chest radiograph shows a small hilar shadow and a small hyperlucent lung on the involved side. The diagnosis may be confirmed and differentiated from Macleod's syndrome by a perfusion lung scan or pulmonary angiogram, both of which show complete lack of perfusion on the affected side. Treatment is not usually possible, although reconstructive anastomotic surgery and recanalization procedures may be practicable in some cases [116]. Rarely pneumonectomy has been required to control haemoptysis, in which case thoracic aortography to demonstrate the collateral circulation is desirable [36].

### **Pulmonary artery stenosis**

Postvalvular pulmonary artery stenosis (syn. pulmonary artery coarctation) is rare and may occur at any level from above the valve to the segmental arteries and beyond [117]. Centrally placed stenoses involving the pulmonary artery trunk or left or right main pulmonary artery branches are less common than multiple peripheral lesions, which are sometimes accompanied by pulmonary hypertension. Although pulmonary stenosis may occur in isolated form, this condition is more commonly detected in the course of the investigation of associated congenital heart disease. Postvalvular pulmonary artery stenosis has been described as part of the rubella syndrome [118] and in idiopathic hypercalcaemia. Chest radiography may show poststenotic dilatations that produce a beaded appearance contiguous with the lung vascular markings. Occasionally the poststenotic dilatations may reach aneurysmal proportions and may rupture causing haemoptysis. The diagnosis is confirmed by pulmonary angiography.

Large centrally placed lesions may be amenable to corrective surgery but this carries the risk of massive intrapulmonary bleeding due to the rupture of more distally placed pulmonary vessels as these are frequently hypoplastic [58].

### **Anomalous origin of the left pulmonary artery**

The failure of the pulmonary arterial plexus of the left lung and the left part of the sixth primitive branchial arch to connect in the normal way may result in the left pulmonary artery arising in anomalous fashion from the right pulmonary artery. In order to reach the left lung, this aberrant left pulmonary artery loops around the right main

bronchus like a sling and runs a peculiar course between the lower end of the trachea anteriorly and the oesophagus posteriorly, thereby crossing the midline to enter the left hilum [119] (Fig. 50.11). A condition known as 'sling' pulmonary artery syndrome may result, in which pressure from the aberrant left pulmonary artery may cause varying degrees of obstruction to the left main bronchus, trachea and oesophagus with consequent dyspnoea and dysphagia. Further tracheal obstruction may be produced in this developmental anomaly by an associated intrinsic tracheal defect, in which the pars membranacea is absent and the lumen of the trachea is completely encircled by so-called 'napkin-ring' cartilages [8]. The aberrant pulmonary sling vessel may be seen on a lateral chest radiograph as a rounded opacity between the air-filled trachea and oesophagus at the level of the carina. A barium swallow may provide supportive evidence and the diagnosis is confirmed by pulmonary angiography [115,120].

### Anomalous systemic pulmonary perfusion

Dysplastic lung tissue may sometimes receive a blood supply from systemic vessels other than the normal bronchial arteries, as has been described in pulmonary sequestration above. Other examples of abnormal systemic arterial supply may be found in the absence of sequestration and where the lung tissue supplied is apparently normal [121,122]. Such arteries usually arise from the descending thoracic aorta but may also originate from the ascending aorta, the arch, the innominate, subclavian, internal mammary and intercostal arteries or below the diaphragm from the abdominal aorta or the coeliac artery [115] (Fig. 50.11). These vessels usually have the characteristic elastic structure of a pulmonary artery, rather than the

muscular form of an aortic branch, and may communicate with the pulmonary circulation or drain systemically, creating a left-to-right shunt. The patient is frequently asymptomatic but may come to medical attention through recurrent haemoptysis. A systolic or a continuous bruit with systolic accentuation may be heard over the involved area of the chest. The chest radiograph may be normal or show increased irregular vascular markings in the vicinity of the anomalous vessels. Pulmonary angiography shows no abnormality, while aortography is diagnostic. Surgical ligation or clipping of anomalous vessels, therapeutic embolism or even resection of lung may occasionally be indicated to control haemoptysis. These anomalies may be classified as a rare form of pulmonary arteriovenous malformation (see below).

### Anomalous pulmonary venous drainage

Anomalous venous drainage of a lung arises as a result of persistent communications between the embryonic system of cardinal veins and the pulmonary venous plexus. These communications develop into aberrant pulmonary veins that drain systemically, usually into the inferior vena cava, rather than returning oxygenated blood into the left atrium in the manner of normal pulmonary veins. This anomalous drainage, which is usually partial rather than total, creates a left-to-right shunt and as with other developmental abnormalities of the lungs may be associated with congenital heart disease, the extent of which may govern the prognosis [123,124].

### Scimitar syndrome

The scimitar syndrome is synonymous with congenital pulmonary venolobar syndrome and vena cava bronchovascular syndrome [123–125]. The most consistent feature of the syndrome is drainage of part of the right lung by an anomalous scimitar-shaped pulmonary vein that passes through the lung running parallel to, but separate from, the mediastinal structures before joining the inferior vena cava, usually below the diaphragm. Other variable features that may be present include:

- 1 an anomalous systemic arterial supply to the territory drained by the scimitar vein, taking the form of multiple small arteries arising from the descending aorta, often below the diaphragm and entering the base of the right lung, the right main pulmonary artery being frequently small or even absent;
- 2 hypoplasia of the right lung itself, which is small and contains fewer airways that may show bronchial isomerism [125];
- 3 cardiac dextroposition, which is a consequence of the small right lung;
- 4 diaphragmatic abnormalities in which the right hemidiaphragm may have an accessory leaf, being fused

Fig. 50.11 'Sling' left pulmonary artery. (After Kale *et al.* [120].)

anteriorly but separated posteriorly and containing lung between its layers [126,127].

The scimitar syndrome may occur familiarly with an autosomal dominant pattern of inheritance [128]. The left-to-right shunt in these patients is usually of insufficient magnitude to produce ill-effects and the condition is most frequently diagnosed in adult life in asymptomatic subjects following a routine chest radiograph [124]. The chest radiograph shows a characteristic curvilinear vascular density in the right lower lung (from which the syndrome derives its name), with features of ipsilateral loss of lung volume as evidenced by mediastinal shift to the right and an elevated diaphragm (see Fig. 50.5). The abnormalities may be demonstrated in detail by CT and pulmonary angiography, although plain radiographs are usually adequate for diagnostic purposes and surgical intervention is in any case rarely necessary [126,129,130].

### Other variant syndromes

Further examples of anomalous pulmonary venous drainage that have been described include the following.

- 1 Drainage of the right lung into the superior vena cava, azygos vein or right innominate vein.
- 2 Drainage of the left lung into a left-sided superior vena cava or vertical vein, representing a persistence of the embryonic left anterior cardinal vein. This vessel may drain in a cephalic direction to join the left innominate vein or caudally to join the coronary sinus.
- 3 Drainage of the pulmonary veins into the coronary sinus attached to the right atrium.
- 4 Drainage of a common single pulmonary vein into the right atrium by way of an additional atrium-like chamber, an anomaly referred to as a cor triatriatum deformity [58,131].

### Pulmonary arteriovenous malformations and telangiectasia (see also Chapter 42)

Several terms used synonymously with pulmonary arteriovenous malformation are found in the literature, including pulmonary arteriovenous fistula, pulmonary arteriovenous aneurysm, pulmonary angioma, pulmonary haemangioma and pulmonary cavernous angioma.

### Definition and pathology

These lesions, although sometimes categorized as tumours, contain no neoplastic cells and are in fact developmental anomalies in which there are persistent vascular communications between arteries and veins within the lung that effectively bypass parts of the normal pulmonary capillary bed. Arteriovenous malformations are rare, approximately three per year having been recorded

at a major North American centre of referral over a 20-year period [132]. Le Roux [133] reported less than one case per year in a European thoracic surgical centre compared with approximately 300 cases of bronchial carcinoma and 13 bronchial adenomas seen in the same period. The majority of arteriovenous malformations probably originate during the development of the primitive pulmonary vascular plexus, when an anastomotic vessel arises which presents a significantly lower resistance to flow than that provided by the surrounding pulmonary vascular bed [58] (Fig. 50.12). Physical principles dictate that arterial blood is diverted through this passage of least resistance, and with increasing flow there is a gradual dilatation and enlargement both of the anastomotic vessel and of the arteries and the tributaries that feed it. Those veins draining the fistulous communication also distend and become varicose. The ultimate size of the lesion depends upon haemodynamic factors and ranges from the very small to a large labyrinthine mass of dilated interconnecting thin-walled vascular spaces of lobar proportions [135].

About 95% of arteriovenous malformations derive their blood supply from branches of the pulmonary artery and drain into the pulmonary venous circulation [132]. In the few remaining cases, the supplying vessels originate systemically from the aorta and innominate, subclavian, internal mammary, bronchial and intercostal arteries and drainage may be via systemic or pulmonary veins [136].

Pulmonary telangiectasis results if there is a fistulous communication between a small peripheral arteriole and venule. If large numbers of these defects are present and if they are diffusely distributed, then the condition may be referred to as pulmonary telangiectasia [137,138].

There is a close association between pulmonary arteriovenous malformations and hereditary haemorrhagic telangiectasia (Osler-Rendu-Weber syndrome), an autosomal dominant condition present in 50–60% of cases [132,139,140]. Conversely, only 5–15% of patients with hereditary haemorrhagic telangiectasia develop pulmonary arteriovenous malformations [141]. It has been shown that a gene located on chromosome 9q3 is strongly associated with the presence of the two conditions, whereas those subjects with Osler-Rendu-Weber disease without pulmonary telangiectasia do not have this abnormal gene [142–144].

Arteriovenous malformations are slightly more common in women than men [108,115]. The majority occur as single lesions, multiple malformations being found in 20–30% of cases, occurring more frequently in patients with hereditary haemorrhagic telangiectasia [108,109]. Approximately 10% of lesions occur bilaterally [132,133]. Arteriovenous malformations are usually closely related to the visceral pleura and 70% occur in the lower lobes [132]. Associated vascular anomalies have been recorded in other organs [140].

**Fig. 50.12** (a) Chest film shows abnormal vascularity in left upper zone. (b) Retrograde aortic catheter shows the aberrant artery supplying lung directly from the aorta.

### Clinical features

It is unusual for discrete arteriovenous malformations to be diagnosed before the third decade of life; hereditary haemorrhagic telangiectasia also usually manifests itself at puberty or later. In a series of 101 cases of all types of pulmonary arteriovenous malformation, the mean age at diagnosis was 40 years [132,145]. However, occasionally the condition is detected in infancy, especially in patients

with hereditary telangiectasia, and in some such cases treatment becomes necessary [146,147]. More than half of all patients have no symptoms referable to the malformations at the time of diagnosis, which is frequently made following a routine chest radiograph or during the investigation of hereditary haemorrhagic telangiectasia. This condition is characterized by the presence of small, raised, red telangiectatic lesions of 2–3 mm diameter that blanch on pressure and are found on the skin and mucosal

**Fig. 50.13** (a–c) Evolution of a convoluted vascular malformation from congenital precapillary arteriovenous malformations. (After Cope [134].)

surfaces, particularly about the face, lips, mouth and nasopharynx (Fig. 50.13). The mucosal lesions tend to bleed and the patient may present with epistaxis, an acute gastrointestinal bleed or symptoms of anaemia as a consequence of occult bleeding into the gut.

The respiratory symptom most commonly present at the time of diagnosis is dyspnoea, haemoptysis being less frequent [132,148]. A bruit is audible in over half of all patients with arteriovenous malformations [132,149]. This is typically heard over the site of the lesion and is systolic or continuous with systolic and inspiratory accentuation. Cyanosis may be present as a result of right-to-left shunting and, when this is present, finger clubbing is a frequent accompaniment [132,150]. Symptoms are unlikely to occur in the case of single discrete lesions provided that the radiographic diameter of the malformation is less than 2 cm. The frequency of symptoms need not be greater in the presence of multiple lesions with the exception of the numerous tiny lesions found in the syndrome of pulmonary telangiectasia, in which symptoms and signs are usually evident from childhood [137,138].

### Complications

The most common complication is haemorrhage, either into the bronchial tree producing haemoptysis or rarely into the pleural cavity producing a haemothorax [151–155]. Exceptionally pneumothorax may occur. Transient cerebral ischaemic attacks or cerebral infarction may be produced by a combination of systemic arterial

hypoxaemia and secondary polycythaemia, while in some series as many as 50% of patients have had episodes suggestive of paradoxical embolization [132,156,157]. Less frequently, cerebrovascular accidents may result from the rupture of an associated intracranial arteriovenous malformation or from an embolus arising within a pulmonary arteriovenous malformation or passing through it in paradoxical fashion [157]. Bacterial endangitis may occur with a pulmonary arteriovenous malformation, giving rise to metastatic abscesses in the brain or at other sites [156]. Cerebral abscesses may also occur if infected material passes straight through an arteriovenous malformation rather than being filtered by the pulmonary capillaries.

### Radiographic features

Arteriovenous malformations may be seen on the chest radiograph as one or more rounded lobulated or tortuous opacities, frequently occupying the periphery of the lower lung fields [133]. Feeding or draining vessels that link the malformation with the hilum are sometimes visible on either plain films or tomograms [158]. CT is a useful method for identification and delineation of lesions [159]. Vascular calcification is uncommon [145]. Serial radiographs may show gradual enlargement of the malformations with the passage of time. The shadows are often well defined and the radiograph may be misinterpreted as indicating metastatic tumour [145]. The radiographic size of the discrete lesion may be shown to vary according to intrathoracic pressure, increasing in size during a Müller manoeuvre and becoming smaller with a Valsalva manoeuvre [160]. Bilateral pulmonary angiography confirms the diagnosis in all but a few cases [158] (Fig. 50.14). This investigation, together with CT, should always be undertaken if surgical treatment is being

**Fig. 50.14** (a) Facial appearance of 10-year-old girl, cyanosed from birth, with Osler–Rendu–Weber syndrome showing cyanosed lips and an angioma on her tongue (arrowed). (b) Finger clubbing in the same patient.

considered since they may demonstrate small lesions not detectable on plain radiographs. In the few malformations that derive their arterial supply from systemic vessels, aortography is required in order to demonstrate them adequately.

The radiographic appearance of pulmonary telangiectasia differs in that the salient feature is diffuse nodularity,

particularly in the lower zones, which may be mistaken for pulmonary fibrosis and which may increase as time passes. As the vascular lesions in pulmonary telangiectasia are small, they are not usually demonstrable by pulmonary angiography.

#### Functional abnormalities

The majority of pulmonary arteriovenous malformations produce a right-to-left shunt, an exception being those lesions with a systemic arterial supply. If the shunt is of sufficient size, arterial hypoxaemia results. However, this is usually mild and is associated with a normal or reduced  $PCO_2$ . In such cases,  $SAO_2$  is reduced and is not entirely correctable by the administration of pure oxygen. The size of the intrapulmonary shunt, expressed as a percentage of cardiac output, may be obtained from measurements of mixed venous and arterial oxygen content while the patient is breathing 100% oxygen for 20 min [161]. Dye dilution curves are of little value in the quantification of shunt in pulmonary arteriovenous malformations because the fistulae are so close to capillary level that two separate peaks of dye are not seen at the arterial sampling site [145]. The former technique may also be inaccurate in the case of pulmonary telangiectasia, in which the proximity of the abnormal vessels to the alveoli and their small size (relative to larger discrete arteriovenous malformations) permits them to take up significant quantities of oxygen when this is being breathed in pure form. An alternative method of determining shunt has been developed in order to overcome this difficulty, by means of radioactively labelled albumin macroaggregates injected into a peripheral vein. Normally almost all of these particles would be arrested in the pulmonary capillaries, but in pulmonary telangiectasia a significant quantity pass straight through the telangiectatic vessels. Since the proportion of cardiac output normally received by the cranial and renal circulations is known, the size of the shunt may be estimated by counting radioactivity over the lungs, brain and kidneys [137,162].

Secondary polycythaemia was present in 23% of a combined series of 101 patients with arteriovenous malformation, anaemia due to hereditary haemorrhagic telangiectasia being present in 19% [132,145]. Right heart and pulmonary artery pressures were recorded in 22 patients in this series and the values obtained were normal in all cases. However, pulmonary hypertension, the mechanism of which is uncertain, has been reported in a few cases [163].

Measurements of diffusing capacity using carbon monoxide ( $DLCO$ ) require correction for haemoglobin level if polycythaemia or anaemia is present [164].  $DLCO$  may be reduced in pulmonary telangiectasia, presumably as a result of a diminished pulmonary capillary blood volume [136].

**Fig. 50.15** Pulmonary arteriogram in patient with multiple arteriovenous malformations.

### Treatment

The more widespread availability of embolization techniques and studies of their success rates and complications has led to a reappraisal of management of arteriovenous malformations, and it is now generally agreed that active treatment is desirable for lesions with feeding vessels greater than 3mm in diameter [165–168]. Indeed, the relatively high rate of complications in untreated malformations is regarded by some as a reason for screening of relatives of patients with hereditary haemorrhagic telangiectasia in order to detect and treat asymptomatic lung lesions. Surgical treatment should be considered following full evaluation of a solitary pulmonary arteriovenous malformation. Discrete peripheral arteriovenous malformations may be removed by local resection with ligation of the afferent and efferent vessels. Deeper and more extensive lesions may be removed by wedge resection, segmental

resection or lobectomy with the general aim of conserving as much lung tissue as possible [145,160]. When the arteriovenous malformations are multiple or bilateral, selective treatment is indicated and embolization or occlusion techniques, using balloons or steel coils, have been used with success. The occluding devices are lodged in a distal part of the feeding vessels. These methods have become the treatment of choice in patients with multiple or bilateral arteriovenous malformations in order to avoid the need for extensive or repeated surgery [165–168]. Complications occur in around 10% of embolizations, including systemic displacement of the embolus and puncture of the myocardium. Nevertheless, these forms of therapy result in increased  $Pao_2$  and improved exercise tolerance, and recanalization is relatively infrequent.

Finally, in some cases of multiple lesions and telangiectasia with cyanosis, lung transplantation becomes an option [169].

ANTHONY SEATON

## Alveolar haemorrhage

Intrapulmonary bleeding occurs in many lung disorders. In general, two patterns are discernible: bleeding from the main conducting airways, as in carcinoma, may be distributed to peripheral areas of the lung but most of the bleeding becomes evident as haemoptysis; in contrast, when bleeding occurs distal to the mucociliary transport system, much or even all of the blood may remain in the lung. This form of alveolar haemorrhage may cause haemoptysis but is also associated with breathlessness, anaemia, hypoxaemia and diffuse pulmonary shadowing.

## Causes

The common causes of alveolar haemorrhage are shown in Table 51.1. Goodpasture's syndrome consists of alveolar haemorrhage/haemoptysis and nephritis [1], and is now further classified into four main conditions: antiglomerular basement membrane antibody disease [2–7], the vasculitides and collagen vascular disorders (although not all cases are associated with nephritis) [8–18], idiopathic rapidly progressive glomerulonephritis [4,12,19,20], and D-penicillamine-induced disease [21,22].

Alveolar haemorrhage may also result from chemical insults such as exposure to trimellitic anhydride [23] and as a consequence of lymphangiography [24], and has been described with azathioprine sensitivity [25] and following exposure to hard metal (tungsten carbide) [26]. Finally, idiopathic pulmonary haemosiderosis is a syndrome of alveolar haemorrhage of unknown cause without involvement of other organ systems. In most series of Goodpasture's syndrome, the vasculitides account for 40–60% of cases of alveolar haemorrhage, idiopathic rapidly progressive glomerulonephritis for 15–30% and antibasement membrane antibody disease for 20–40% [4,7,12]. This section is principally concerned with antibasement membrane antibody disease as a cause of Goodpasture's syndrome and with idiopathic pulmonary haemosiderosis. The other causes of Goodpasture's syn-

drome and alveolar haemorrhage are discussed in the chapters indicated in Table 51.1.

## Antiglomerular basement membrane antibody disease

### Definition

This disease is characterized by alveolar haemorrhage and glomerulonephritis with linear deposition of IgG on the basement membranes of glomeruli and alveoli. Circulating antibodies to glomerular basement membrane can be detected in the blood [3,5–7].

### Aetiology and prevalence

Between 1980 and 1984, 71 patients with this condition were reported in the British Isles [6], although this is certainly an underestimate, and the disease is now thought to occur in rather fewer than 1 per million of the population annually [6]. The peak incidence is seen between 20 and 30 years of age with a 4:1 male predominance. A second peak is seen in middle age where women in their sixties may present with glomerulonephritis alone [6].

The precipitating factor for the disease is unknown, although some cases have followed exposure to hydrocarbon vapour [27] and study of workers exposed to petroleum mineral oils have shown an excess of antibasement membrane antibodies [28]. In other cases, including the original description by Goodpasture, the illness has been preceded by a viral infection. The distinguishing feature of the disease is the presence of circulating antibody to glomerular basement membranes, with linear deposition of this antibody on alveolar and glomerular basement membranes [29]. The antigen to which the antibody is directed is located in the C-terminal domain of type IV collagen from glomerular and alveolar basement membrane and has a molecular mass of 26 000 kDa [30–33]. It has been shown that the antigen is the non-collagenous part of the  $\alpha_3$  chain of type IV collagen, expressed by a gene in the

q35–37 region of chromosome 2 [34,35]. The pathogenesis is believed to involve a cytotoxic type II hypersensitivity reaction consequent on antibody binding to this antigen. Certainly the disease can be passively transferred to monkeys by administration of human anti-glomerular basement membrane antibody and the severity of the disease is proportional to the titre of circulating antibodies [36]. Savage and colleagues [6] reported a peak incidence of the disease in spring and early summer, which might be consistent with a viral trigger factor. Genetic factors would also appear to have some importance; cases have been reported in identical twin sisters living together and in two brothers who lived apart [37,38]. In addition, there is a strong association with HLA-DR2, which is present in 60–70% of cases [39–41]. It is tempting to speculate that, in those genetically predisposed, infection with a virus that shares a similar antigen to the Goodpasture antigen may precipitate disease. Such an association with influenza A2 virus infection has been described [42].

It thus seems likely that pulmonary haemorrhage occurs as a result of damage to type IV collagen in alveolar basement membrane and that, particularly in the genetically predisposed, this may occur as a consequence of a number of trigger factors, which may include viral infection and inhaled or ingested toxic substances. Type IV collagen is important in protecting the pulmonary capillaries from physical stress, and when weakened allows leakage of blood [43]. Other factors may damage collagen in the lung, perhaps explaining why cigarette smokers are at greater risk of Goodpasture's syndrome [44]. In most cases the renal lesion is presumably a consequence of the anti-

collagen IV antibodies also attacking the collagen of the glomerular basement membrane.

### Pathology

Renal biopsy shows a diffuse crescentic or focal glomerulonephritis or even, rarely, normal glomeruli [2,45]. Linear deposits of IgG can be detected on the glomerular basement membrane using immunofluorescence techniques. Occasionally, immunofluorescent stains for IgA, IgM, the C3 component of complement and fibrinogen are positive [46]. Similar techniques can be applied to lung tissue obtained by open, needle or transbronchial biopsy in order to demonstrate linear deposition of IgG on alveolar basement membranes [47,48]. Light microscopy of lung biopsies shows active intra-alveolar haemorrhage with collections of haemosiderin-laden macrophages [46].

### Functional abnormality

Where measured, a restrictive pattern of lung volumes is usually found. The diffusing capacity for carbon monoxide ( $DLCO$ ) is increased during episodes of haemorrhage as a result of sequestration of blood within the alveoli. The single-breath diffusion coefficient for carbon monoxide ( $Kco$ ) is considered abnormal if raised by more than 30% and serial measurements are of considerable value in monitoring the progress of alveolar haemorrhage [49–52]. Although  $Kco$  frequently parallels the extent of airspace shadowing on the chest radiograph, it may also increase in the presence of a persistently normal film or alternatively precede the development of shadowing by up to 48 h [53].

### Clinical and radiological features

There is often a preceding upper respiratory tract infection [2,3,5,6,12,54–58]. Haemoptysis is found in 80–90% of presentations and is more common in smokers. In one series of 51 patients, 100% of smokers with this disease developed pulmonary haemorrhage while only 20% of non-smokers did so [44]. Cough, dyspnoea, weakness and fatigue are common complaints. Fever and chills may occur. Pallor is common and hypertension is found in a minority of cases. Auscultation of the chest frequently reveals inspiratory crepitations. The chest radiograph is abnormal in over 80% of cases and most commonly shows diffuse bilateral patchy consolidation in the mid and lower zones with relative sparing of the apices and costophrenic angles (Fig. 51.1). Air bronchograms may be seen. Urinalysis is abnormal in over 90% of patients, with microscopic haematuria, proteinuria, granular casts and occasionally frank haematuria. An iron-deficiency anaemia is usual and uraemia is found in over 70% of cases. Examination of sputum or bronchoalveolar washings reveals the presence of blood

**Fig. 51.1** Radiograph of patient acutely dyspnoeic with Goodpasture's syndrome showing extensive bilateral consolidation and air bronchograms.

and/or haemosiderin-containing alveolar macrophages. Occasionally renal involvement without pulmonary haemorrhage or pulmonary involvement without obvious renal disease may occur [3,6,45].

### Differential diagnosis

The differential diagnosis includes the disorders listed in Table 51.1. Drug or chemical-related disease is readily identified by taking a history. The vasculitides and collagen vascular diseases frequently have other systemic manifestations (see Chapters 40 & 53) that assist in diagnosis. Idiopathic rapidly progressive glomerulonephritis is diagnosed when a renal biopsy shows crescentic glomerulonephritis without arteritis or linear immunofluorescence in the absence of any other features of a multisystem disorder. Nevertheless, it is managed in the same way as the vasculitides. It has been suggested that it is a variant of Wegener's disease, with antineutrophil cytoplasmic antibodies [59]. The definitive diagnosis of antiglomerular basement membrane disease is made by demonstrating linear immunofluorescence (usually to IgG) on the glomerular basement membrane (less commonly the alveolar basement membrane) and by detecting an elevated titre of antiglomerular basement membrane antibodies in the serum using radioimmunoassay or enzyme-linked immunosorbent assay [60].

### Treatment and progress

The condition often presents to the chest physician as rapidly increasing haemoptysis with progressive renal failure, although there is frequently a history of previous

smaller haemoptyses. While spontaneous remission may occur, the course is usually progressive and fatal unless treated [61–63]. The renal manifestations require treatment with high-dose prednisolone (60 mg daily reducing to 20 mg over 4 weeks) and cyclophosphamide (2–3 mg/kg daily). As the patient responds, the cyclophosphamide may be stopped after about 2–3 months and the prednisolone tailed off and stopped within about 6 months.

The addition of plasmapheresis to immunosuppression has improved the speed of response and effectiveness of the above regimen and in general a good response can be expected if the patient is not already oliguric at the time of presentation [64]. Usually this is associated with resolution of the pulmonary haemorrhage within a few days and recovery of renal function. The plasma exchange is usually continued for about 2 weeks until the antibasement membrane antibodies are reduced to baseline levels. There has been one report of successful treatment of a patient unresponsive to plasmapheresis by immunoadsorption of IgG to staphylococcal protein A [65]. In patients with severe renal failure, dialysis may be necessary and ultimately transplantation if recovery does not occur. In this case, the operation should be delayed until antiglomerular basement membrane antibodies have fallen to low levels [3]. In exceptional cases bilateral nephrectomy has been necessary to control alveolar haemorrhage when all else has failed [3,66].

Relapse of disease may occur during treatment, when it is more often due to an intercurrent infection than to a rise in antibody titres [67]. Once successfully treated, recurrence is rare but has been reported, on one occasion following exposure to hydrocarbon solvents [68–70]. Lung

function often shows permanently reduced gas transfer [71] and sometimes there is a slow decline in renal function. If relapse does occur, it is likely to respond to the same regimen as described above.

### **Idiopathic pulmonary haemosiderosis**

Idiopathic pulmonary haemosiderosis is a condition of uncertain cause characterized by recurrent episodes of alveolar haemorrhage, haemoptysis and secondary iron-deficiency anaemia. Most cases begin in childhood but some start in adult life. The disease is often fatal though apparently complete recovery can occur.

### **Aetiology and prevalence**

This is a rare disease but in 1962 Soergel and Sommers [72] were able to review 132 cases from the literature and from personal experience. Most were aged 1–7 years at onset but about 15% were aged 16 or over when symptoms began. The sex distribution was equal in childhood but in adult life the disease was twice as common in men. The disease is not familial and from the number of different associations recorded in the literature it seems likely that its aetiology is multifactorial.

The accompanying iron-deficiency anaemia is certainly due to loss of iron into the lung through haemorrhage, as has been shown by iron turnover studies, although the cause of the haemorrhage is uncertain [73]. Epidemiological observations in northern Greece have shown an excess of cases in poor rural areas where toxic insecticides were often applied to cereals stored within or close to the dwelling place [74]. A reduction in case numbers was seen when these conditions were improved, possibly implicating insecticides in the pathogenesis.

Immunological causes are fashionable and might be supported by the presence of eosinophilia in one-eighth of cases, the aggregation of mast cells in the lung, an increase in plasma cells in the reticuloendothelial system and the presence of cold agglutinins in some cases [75,76]. Immunological diseases that have been associated with pulmonary haemosiderosis include rheumatoid arthritis, autoimmune haemolytic anaemia, dermatitis herpetiformis, thyrotoxicosis and coeliac disease [77–82]. In addition, children and adults have been described with idiopathic pulmonary haemosiderosis secondary to gluten enteropathy and cows' milk allergy who responded clinically to withdrawal of gluten and cows' milk respectively [75,83–85]. Nevertheless, the aetiology in the majority of cases remains unknown.

### **Pathology**

Histologically, there is degeneration, shedding and hyperplasia of alveolar epithelial cells with marked localized

alveolar capillary dilatation [72]. Haemosiderin-containing macrophages are plentiful in the alveolar spaces and interstitium [86,87]. Depending on the chronicity of the condition there may be varying degrees of interstitial fibrosis, degeneration of the alveolar, interstitial and vascular elastic fibres, dilatation and moderate subendothelial sclerosis of pulmonary arteries and veins, and slight muscular hypertrophy of the bronchial arteries. These changes are secondary to the recurrent bleeding [72]. Electron microscopic examination has shown widespread capillary endothelial and basement membrane damage [88,89]. Deposits of protein, in one case characterized as IgA, have occasionally been observed on the alveolar basement membrane [79,88].

### **Functional abnormality**

In acute incidents of alveolar haemorrhage *Kco* is elevated, values of greater than 130% predicted being considered abnormal [49,50]. In chronic cases, where interstitial fibrosis has developed, a restrictive pattern of lung volumes and reduced *DLco* is usual, although a pattern of airways obstruction is also seen in some patients [82,87].

### **Clinical and radiological features**

The intensity and duration of the pulmonary haemorrhages determine the clinical course, which may be very variable [72,79,86,90,91]. Commonly, continuous mild intrapulmonary bleeding results in a chronic non-productive cough with tiredness, pallor and failure to thrive in children. The sputum may be intermittently blood-stained or the child may vomit swallowed blood. An iron-deficiency anaemia is usual and the faecal occult blood test may be positive. A minority of patients may have generalized lymphadenopathy or hepatosplenomegaly. The chest radiograph may show transient blotchy shadows. With a severe bleed, cough and haemoptysis worsen and dyspnoea, chest pain or tightness and pyrexia may develop. The anaemia worsens and the chest radiograph is likely to show more extensive, bilateral, patchy shadows particularly in the middle and lower zones. Crepitations may be audible in the chest.

Bleeding episodes continue for years and eventually chronic dyspnoea becomes a feature in addition to the anaemia. Finger clubbing develops in 25%. The chest film may show reticulonodular infiltrates, fine stippling or a ground-glass appearance in the perihilar or lower lung zones due to pulmonary fibrosis. The apices and costophrenic angles are often spared. Hilar lymphadenopathy is occasionally seen. Cor pulmonale secondary to pulmonary fibrosis and hypoxaemia develop in a minority [92]. Massive pulmonary haemorrhage may occur at any time and most patients die in a severe bleeding episode.

### Investigations

Haemosiderin-laden macrophages are found in sputum or bronchial washings. A hypochromic microcytic anaemia is usual and a minority of blood films show an eosinophilia [72]. Idiopathic pulmonary haemosiderosis is a diagnosis of exclusion and no evidence of other organ involvement is found, although confusion with Goodpasture's syndrome before renal disease presents may lead to diagnostic problems. Diagnosis depends on excluding other causes of pulmonary haemorrhage, especially those such as Wegener's syndrome, Goodpasture's disease and microscopic polyarteritis that may require immunosuppressive treatment.

### Treatment

Patients with cows' milk allergy or gluten enteropathy have responded to withdrawal of the offending substance [83–85]; unfortunately, these patients are a small minority. Iron-deficiency anaemia responds to replacement therapy and occasionally blood transfusion is required during severe bleeding episodes. Corticosteroid and immunosuppressive drugs do not appear to affect the long-term prognosis but either may be of value during acute episodes of alveolar haemorrhage, as in Goodpasture's syndrome [93]. Anecdotal reports of therapeutic success with assorted agents such as sodium cromoglycate (cromoglycate) [76] and budesonide [94] abound. However, the disease may remit spontaneously and these reports should be viewed with caution.

### Prognosis

The course of the disease is very variable. Although it is often fatal, a number of patients appear to recover and remain symptom-free for long periods. Soergel and Sommers [72] found that 20 of 68 patients were dead after an average duration of disease of 3.3 years; 17 still had active disease after an average duration of 5.5 years; 12 had relatively inactive disease but still with chronic symptoms, such as exertional dyspnoea and anaemia, after an average duration of 5.4 years; and 19 were apparently completely free of the disease and symptoms after an average duration of 4.5 years. These authors contrast a 28-year-old woman who died after an illness of only 9 days and a boy aged 6 years at onset who died of cor pulmonale 20 years later.

## Pulmonary alveolar proteinosis

First described in 1958 by Rosen and colleagues [95], pulmonary alveolar proteinosis is a rare disease of unknown origin characterized by progressive dyspnoea, febrile episodes and a cough that is usually unproductive. The

radiological appearances are often similar to those of pulmonary oedema. Histologically, the alveoli contain a granular eosinophilic material strongly positive to periodic acid–Schiff (PAS) stain.

### Aetiology

The disease is three times as common in men as in women and usually occurs in young adults, although it has been described in the neonatal period, in children and in old age [96,97]. Primary alveolar proteinosis is characterized by uniform immunoperoxidase staining of the specific surfactant apoprotein in alveoli [98,99]. Two surfactant proteins, Sp-A and Sp-D, have been described in alveolar fluid from such patients [100,101]. Secondary alveolar proteinosis, which is found in association with immunosuppression due to haematological malignancy [102–106], myeloma [107], hypogammaglobulinaemia [108] or, more recently, human immunodeficiency virus (HIV) infection [109,110], shows only focal immunoperoxidase staining of the specific apoprotein [98]. Congenital alveolar proteinosis was first described in four siblings [111] and appears to be associated with an inherited deficiency of Sp-B [112]. The syndrome has also been described in children with a recessive amino acid transport disease, lysinuric protein intolerance [113]. Opportunistic infections, especially *Nocardia*, *Aspergillus*, *Mycobacterium* and *Cryptococcus* spp., are common in secondary alveolar proteinosis but rare in the primary condition [105,114]. Exposure to aluminium or silica dust has been associated with alveolar proteinosis and the condition can be produced in experimental animals by inhalation of large doses of finely divided mineral dust [106,115].

Pulmonary alveolar proteinosis is believed to be due to a failure of reprocessing of surfactant by type II alveolar cells, with resultant accumulation of phospholipid and glycoprotein-rich material in the alveolar spaces [116]. Electron microscopy of the alveolar material shows myelin-like multilamellated structures, which represent phospholipid bilayers separated from each other by amorphous proteinaceous material [117]. The glycoprotein has been isolated and characterized and appears to be a monomeric and dimeric form of the surfactant glycoprotein found in normal alveolar lining fluid [118,119]. Macrophage numbers are diminished in bronchoalveolar lavage fluid from patients with alveolar proteinosis and the cells may be increased in size [120,121]. The macrophages also have diminished phagocytic capacity, with decreased phagolysosome fusion [121,122]. These phagocytic defects can be induced in mouse peritoneal or human macrophages on exposure to cell-free fractions of the alveolar material, suggesting that the macrophage defect is secondary and not primary [121,122]. Leukotriene (LT)C<sub>4</sub>-like substances and LTB<sub>4</sub> have been found in significant quantities in alveolar proteinosis

lavage fluid, although the source and their contribution to the pathogenesis of the disease are not clear [123].

### Pathology

Macroscopically, the lungs contain firm, grey-white, nodular or diffuse masses, which microscopically consist of alveoli, bronchioles and bronchi stuffed with eosinophilic granular material staining with PAS (Fig. 51.2). Bronchial and alveolar walls may be infiltrated by lymphocytes. The alveoli are often lined by flattened epithelial cells and occasional foamy mononuclear cells containing lipoid. In frozen sections, long, thin, birefringent crystals may be present. A few cases may have some interstitial fibrosis.

### Functional abnormality

The extent of the abnormality depends on the amount of lung involved. A restrictive pattern of lung volumes with reduced *DLCO* is usual and hypoxaemia, which may be extreme, occurs. The ratio of forced expiratory volume in 1 s to forced vital capacity is usually normal.

### Clinical features

The usual presentation is with progressive dyspnoea on exertion with or without a dry unproductive cough [116,120,124,125]. Weight loss, chest pain and fever may also occur. The initial presentation is often wrongly diagnosed as pneumonia, sarcoidosis, allergic alveolitis or tuberculosis; in one series the median interval between onset of symptoms and diagnosis was 2 years, with a range of 6 weeks to 6 years [124]. Fine inspiratory crackles may be audible in the chest and finger clubbing develops in a minority.

### Radiology

The chest film most often shows diffuse perihilar shadows resembling pulmonary oedema (Fig. 51.3). Peripheral nodular and lobar consolidation may also occur [126,127]. There may be numerous cyst-like translucencies possibly due to pneumatoceles from bronchial obstruction. Occasionally, shifting densities may suggest pulmonary eosinophilia. Changes in the radiological appearances are not always related to changes in the patient's symptoms, and clinical improvement may coincide with radiological deterioration and vice versa. Sometimes the initial radiographic appearances may suggest interstitial fibrosis [128,129]. In children, the radiographic appearance may differ from the classical adult picture; reticulonodular and miliary nodular patterns have been recorded as well as focal consolidation [97].

### Investigations

Sputum or bronchial washings contain PAS-positive, alcian blue-negative staining material. Lamellar bodies may be seen on electron microscopy [130]. Serum lactate dehydrogenase levels may be elevated [131].

### Treatment

A number of patients with this condition (25% in one series [120]) improve spontaneously and do not require treatment. Spontaneous remission for 18 years has been reported [132]. However, the majority require treatment for progressive symptomatology and deteriorating pulmonary function. The treatment of choice is unilateral lung lavage while the contralateral lung is isolated and ventilated by using a double-lumen endobronchial tube [116,124,133]. The lavage lung is filled with saline buffered

to pH7.4 at a temperature of 37°C and volumes of 500–1000 mL are washed in and out until a total of 40–50 L has been exchanged or the effluent has become clear. At the conclusion of the procedure, vigorous suction and manual ventilation are followed by a short period of assisted ventilation. The second lung can be lavaged at a later date. Not surprisingly, chest radiographs taken during the lavage procedure show worsening of the pulmonary shadowing; within a few hours the chest film may

have deteriorated further or improved but thereafter there is a gradual improvement at 1 week and marked to moderate improvement at 6 weeks [134]. Lavage may need to be repeated at intervals, the frequency varying between individual patients. Lavage via the fiberoptic bronchoscope is less satisfactory than the above but has been successfully employed to treat the right middle and upper lobes in a patient with only one lung [135].

In patients who are too hypoxic to undergo lung lavage,

various forms of support, including hyperbaric oxygen [136], use of a membrane oxygenator [137] and partial cardiopulmonary bypass [138], have been employed to maintain  $P_{aO_2}$  during the procedure. In one patient who refused bronchopulmonary lavage a satisfactory response was obtained to treatment with ambroxol, a surfactant activator [139].

### Prognosis

The prognosis of primary alveolar proteinosis in adults has been much improved by bronchopulmonary lavage, which helps in 80% of those who require it although it may have to be repeated at intervals to maintain this improvement [120]. Death is more likely to occur in children and in those with secondary alveolar proteinosis, where opportunistic infection and the underlying disease are the main causes.

## Amyloidosis

Amyloidosis is usually secondary to one of the well-recognized causes, although primary amyloidosis of unknown cause may occur. Amyloid consists of protein that shows a characteristic fibrillar pattern on electron microscopy. The amyloid in primary amyloidosis (AL) is formed from the light chains or part of the light chains of immunoglobulin [140]. In secondary amyloidosis the protein differs from that found in primary amyloidosis and is designated AA. Additional amyloid types such as AEt, found with endocrine neoplasms and which is related to calcitonin, have also been described [140]. Both primary and secondary amyloidosis may be generalized or localized to the lung. A convenient classification is shown in Table 51.2.

In generalized amyloidosis, whether primary or secondary, amyloid infiltrates are commonly found in alveolar septa and pulmonary arteries though these lesions seldom give rise to important symptoms, which are more commonly due to amyloid infiltration at other sites, particularly the heart.

Localized primary or secondary amyloidosis may affect the tracheobronchial tree or the pulmonary parenchyma. The most common form of tracheobronchial involvement is with multifocal submucosal plaques, often with diffuse infiltration of the entire airway wall leading to stenosis [141–144] (Fig. 51.4). The less common form of tracheobronchial involvement is with single or multiple amyloid tumour-like masses that are sometimes discovered incidentally at bronchoscopy. Parenchymal involvement is most frequently in the form of single or multiple nodules of 1–15 cm in diameter [145–150] with or without hilar or mediastinal node involvement [151–154]. One case of an isolated mediastinal amyloid mass has been reported [155]. Diffuse alveolar septal involvement with amyloid

\* Including hilar lymph node involvement.

[156] is probably more common than is reported, although only 4 of 157 cases reviewed by Thomson and Citron [141] were in this category.

### Clinical and radiological features

Patients with tracheobronchial involvement are usually in their fifties, on average 10 years younger than those with pulmonary parenchymal involvement [142]. Tracheobronchial lesions come to notice by causing symptoms of obstruction, such as cough, wheeze and dyspnoea, which may be slowly progressive over the years. Parenchymal lesions are often detected on routine radiography when they are usually thought to be carcinoma or, if multiple, metastases [157]. The diagnosis of airway lesions can be established by endoscopic biopsy; pulmonary lesions can also be diagnosed by transbronchial biopsy [158], although this may not be without risk [159]. In secondary cases there is evidence of the primary cause. In some cases this causes diagnostic difficulties, for example when it is confused with rheumatoid, Sjögren's or ankylosing spondylitis lung or the lung disease associated with inflammatory bowel disease [160–163].

Rarely amyloidosis can cause respiratory failure by infiltration of the diaphragm or other respiratory muscles [164,165]. Sleep apnoea due to amyloid macroglossia has also been reported [166].

### Functional abnormality

With extensive nodular or diffuse disease of the pulmonary parenchyma, a restrictive pattern of lung volumes with reduced gas transfer may be seen.

**Fig. 51.4** Left anterior oblique bronchogram of patient with diffuse tracheobronchial amyloidosis showing multiple areas of airway narrowing.

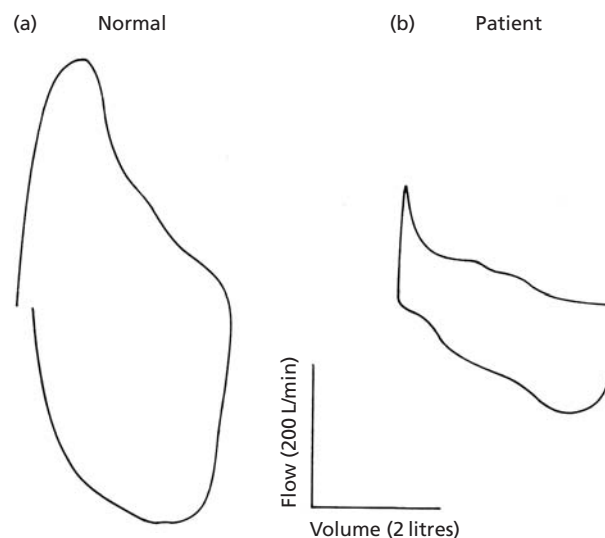

Tracheobronchial involvement may result in an obstructive pattern of lung volumes and sometimes the typical findings of large airway obstruction on flow–volume loops (Fig. 51.5).

#### Treatment

The only possible treatment is surgical. Isolated pulmonary nodules are usually removed (and cured) under suspicion of carcinoma. No treatment is available for multiple pulmonary nodules. Tracheobronchial amyloid may be successfully controlled by endoscopic removal or by laser photoresection [167]. Untreated lesions progress slowly over the years and long survivals have been documented [153]. One patient with primary tracheobronchial amyloidosis treated personally for over 10 years responded clinically to the combination of prednisolone and melphalan. The melphalan was subsequently discontinued but deterioration in symptoms and lung function always followed attempts to stop the steroids.

#### Tracheopathia and bronchopathia osteoplastica

The term ‘tracheopathia osteoplastica’ was first used by Aschoff [168], although Wilks in 1857 [169] was the first to

**Fig. 51.5** Flow–volume loops of (a) normal subject and (b) patient with tracheobronchial amyloid, which shows the severe inspiratory and expiratory obstruction.

report the presence of large numbers of bony plates protruding into the lumen of the larynx, trachea and bronchi of a 38-year-old man dying of pulmonary tuberculosis. The term ‘tracheobronchopathia osteoplastica’ has been

coined to embrace all the possible sites of the disease process [170].

### **Prevalence, aetiology and pathology**

Some 245 cases had been reported in the world literature up to 1974, mostly in middle-aged and elderly men but occasionally in women [171]. Since then there have been regular isolated case reports. The bony or cartilaginous bosses or plaques arise over the cartilages and are continuous with the perichondrium. Histologically, the lesions are of bone, cartilage or calcified acellular protein matrix. The mucosa overlying the protrusions is usually intact and histologically normal, although squamous metaplasia has been reported [171–173]. The lesions may be localized or diffuse and are usually only diagnosed at autopsy, although occasionally they may be diagnosed because they cause bronchial obstruction. While the aetiology is unknown, it has been suggested that metaplastic changes occur in elastic tissue with conversion to elastic cartilage that may then ossify [174]. A simpler explanation is that the protrusions simply represent exostoses and ecchondroses from tracheal cartilage rings [175]. Finally, it has been suggested that the condition may be a late development in tracheobronchial amyloidosis [176].

### **Clinical features**

Most cases have only been diagnosed at autopsy in patients dying of other diseases, although a few have been diagnosed by the characteristic bronchoscopic appearances [177]. Recurrent pneumonia may occur distal to obstruction and lead to a bronchoscopic diagnosis [178]. Minor symptoms may include cough, dry throat, voice change, dyspnoea and haemoptysis. The complaint of haemoptysis frequently leads to diagnosis at bronchoscopy [177].

### **Radiology**

Bronchial obstruction may cause collapse and pneumonia. The condition cannot be recognized on routine radiography, although tomography of the trachea or main bronchi may reveal the characteristic projecting nodules [177,179].

### **Treatment**

Treatment is only necessary for complications such as infection or collapse. If the collapsed lung is not severely damaged, endoscopic removal or sleeve resection of the blocked bronchus might be justified. When the larynx is affected, laser treatment has been used to remove protrusions [180].

## **Alveolar microlithiasis**

Pulmonary alveolar microlithiasis is a disease that is often familial and characterized by a radiographic appearance of very fine, sand-like mottling uniformly distributed through both lungs. This mottling represents an extensive intra-alveolar deposit of calcium-containing bodies. Despite extensive radiographic changes, symptoms at the time of discovery are often minimal or absent, but later there is gradual progression to respiratory failure and cor pulmonale.

### **Aetiology**

The cause of the disease is quite unknown. It may occur at any age between infancy and 80 years but the majority are diagnosed between the ages of 30 and 50 years. The sex distribution is equal. A familial incidence, particularly in siblings, is common, leading to the suggestion that a local defect of calcium metabolism may be responsible [181]. A report from Turkey indicates that the condition seems to be more frequent than would be expected on the basis of reports from elsewhere in the world, 52 cases having been described over 30 years; several of these were also familial [182].

### **Pathology**

The lungs are solid and may sink in water [181], and throughout there are sand-like grains diffusely distributed but maximal at the bases. At necropsy, a saw may be required to cut the lung. Microscopically, there are 'onion-skin' bodies, resembling corpora amylacea, in 30–80% of alveoli and these bodies are usually densely calcified. There may or may not be interstitial fibrosis and inflammatory cell infiltration. Emphysematous blebs may be found at the apices or anterior margins of the lungs. There are usually no changes in other organs, although deposits in the lumbar sympathetic chain and probably in the testes have been reported in one patient [183].

### **Clinical and radiological features**

These patients are often discovered by routine radiography at an asymptomatic stage when they may have no complaints despite dramatic changes on the chest film. Over a period of years there is progression of disease, with the development of increasing dyspnoea, cough and, later still, cyanosis, polycythaemia and cor pulmonale. Haemoptysis occasionally occurs [184] and clubbing may be seen [185]. The patient may occasionally cough up calcified bodies. Recurrent pneumothoraces may occur [186]. There are often no physical signs in the chest even when the radiograph is grossly abnormal. Later there may be inspiratory crepitations and, ultimately, the signs of cor

pulmonale. Death usually results from respiratory or cardiac failure.

### Functional abnormality

Respiratory function tests are often normal or near normal even with extensive radiographic changes. However, with progression of disease, a restrictive pattern of lung volumes develops and impairment of gas transfer with disturbed ventilation-perfusion ratios have been reported [185,187].

### Treatment and prognosis

Therapeutic bronchoalveolar lavage has been shown to be ineffective in one case [185], and it is apparent that in progressive cases the only management course may be lung transplantation. This has been carried out successfully in at least one patient, a 32-year-old man who developed severe pulmonary hypertension [188]. Prior to this extreme measure, there is one report of nasal continuous positive pressure ventilatory support being used to improve gas exchange in a patient with respiratory failure [189].

The disease is probably slowly progressive, although occasionally it appears to arrest. One reported patient was followed for 22 years from diagnosis to death [185].

## Idiopathic pulmonary hilar fibrosis

Chronic idiopathic pulmonary hilar fibrosis is a fibrosing condition restricted to the pulmonary hila that appears to have many similarities to idiopathic mediastinal fibrosis and retroperitoneal fibrosis [190–192]. The aetiology is unknown.

### Pathology

Hilar fibrosis has been classified into two types depending on the relative involvement of the pulmonary artery or vein [190]. In type I disease, the pulmonary artery is narrowed or occluded by the fibrotic hilar mass, with the resultant development of exuberant bronchopulmonary anastomoses. Loss of lung volume is seen on the affected side and pleural thickening occurs due to repeated chest infections and the development of collateral vessels between the lung and chest wall. Narrowing of one of the main bronchi by the fibrotic process is often seen. In type II disease, the main pulmonary veins are occluded by fibrous tissue, with resultant pulmonary capillary hypertension in the affected lung. Loss of lung volume, pleural thickening and narrowing of main bronchi due to the fibrotic process are again seen. The fibrous tissue may extend through the bronchial cartilage. Histologically, the fibrous mass is composed of relatively acellular fibrous

tissue comprising intertwining collagen fibres. The interstices contain a few fibroblasts and lymphocytes with more plasma cells and occasional foci of polymorphonuclear leucocytes. Various degrees of hyalinization, calcification and ossification may be present.

### Clinical and radiological features

Patients commonly present in young adult life with repeated haemoptyses and dyspnoea and there may be clinical signs of pulmonary hypertension. Radiographically, there may be pleural thickening and diminution of the size of the affected lung, and segmental narrowing of one or more major bronchi may be demonstrated at bronchoscopy or with bronchography (Fig. 51.6). The pulmonary artery shadow may be diminished in type I disease and pulmonary angiography shows absent or diminished pulmonary blood flow. In type II disease, an ill-defined hilar shadow may be seen with radiographic evidence of pulmonary venous distension.

### Treatment and prognosis

No form of medical treatment is available. Most patients are subjected to thoracotomy, and resection of the 'tumour' and affected lung is carried out in the belief that the process is malignant. Treatment by simple ligation of bronchial arteries on the affected side also appears to have been effective in one case [190]. Where the condition is unilateral the prognosis, given surgical intervention, appears to be relatively good [190]. Bilateral hilar fibrosis has a poor prognosis when bilateral pulmonary venous obstruction occurs [193,194].

## Pulmonary hyalinizing granuloma

Pulmonary hyalinizing granuloma is a condition of unknown aetiology, usually diagnosed by pathological examination of nodules resected following their discovery on routine chest radiography.

### Pathology

Macroscopically, the waxy white lesions are found in the pulmonary parenchyma or just below the pleural surface [195]. Microscopically, they are seen to be composed of homogeneous pink hyaline lamellae surrounded by plasma cells, lymphocytes and histiocytes, which may also be found locally in a perivascular distribution. Occasional eosinophils and foci of ischaemic necrosis may be seen and foreign body giant cells may be present at the periphery of the lesion. In many of the 20 patients reported by Engleman and colleagues [195] the hyaline material stained with Congo red and had the characteristics of amyloid.

**Fig. 51.6** Chest film of patient with left-sided idiopathic hilar fibrosis who presented with left lower lobe bronchial obstruction and secondary lung abscesses in posterior basal segment.

**Fig. 51.7** Peripheral lesion in right mid zone that on excision proved to be a hyalinizing granuloma.

## Clinical and radiological features

The average age of patients reported by Engleman and colleagues [195] was 45 years, with a range of 27–66 years. The majority were asymptomatic or had only mild symptoms, including cough, haemoptysis, fever, fatigue and pleuritic chest pain. The abnormality was commonly detected on routine chest radiography, which usually showed multiple, frequently bilateral, nodules with no predilection for any particular lung zone. Single lesions also occur (Fig. 51.7). The lesions were usually well defined and round, although irregular ill-defined nodules and cavitation were also seen. Calcification was not present. Lesions tended to grow very slowly, in one case with a doubling time of 2.5 years. The behaviour of the lesions was reminiscent of nodular pulmonary amyloid.

## Treatment and prognosis

Isolated lesions are often resected as suspected carcinomas with resultant cure. No treatment is available for multiple lesions but the prognosis appears to be good, with no significant impact on longevity [195]. Four patients have been reported as developing sclerosing mediastinitis and two retroperitoneal fibrosis [195,196], an association that must be considered signifi-

cant even though the aetiology of all these conditions is unknown.

## Castleman's disease

Two subtypes of the very rare Castleman's disease, angiofollicular hyperplasia, have been described [197,198]. The more common presents as a mediastinal or hilar lymph node mass, usually asymptomatic or with cough or wheeze due to local compression. Occasionally there are febrile symptoms and a raised erythrocyte sedimentation rate. Biopsy at mediastinoscopy shows follicles of pericapillary lymphocytes, with proliferation of the plump and eosinophilic capillary endothelial cells. Patients with this condition generally do not seem to show a progressive illness and symptoms may be relieved by removal of the nodes.

A more aggressive variant, with prominent plasma cell infiltration, may be associated with other systemic manifestations, including generalized lymph node enlargement, hepatosplenomegaly, paraproteinaemia and skin rash. It may require treatment with corticosteroids and sometimes chemotherapy as for lymphoma, though it is thought not to be truly neoplastic but associated with overproduction of interleukin 6. There seems to be some evidence of an association with HIV infection and Kaposi's sarcoma.

# RESPIRATORY INFECTION IN THE IMMUNOSUPPRESSED

R. ANDREW SEATON, JULIAN M. HOPKIN AND DOUGLAS SEATON

Respiratory infection in the immunosuppressed has become a major clinical issue with the advance of human immunodeficiency virus (HIV) and with progress in transplant and oncology programmes. Defence of the lungs against infection is complex, comprising laryngeal and cough reflexes, the mucociliary escalator, the scavenging macrophages of the alveolar spaces, a range of innate immune factors (e.g. mannose-binding protein, surfactant proteins A and D) and acquired T-cell immunoglobulin immunity.

Defects in these defences are various and can produce characteristic syndromes of infection. The first part of this chapter focuses on the general principles of respiratory infection complicating severe deficiency of acquired immunity, most commonly seen among patients on cancer chemotherapy and organ transplantation programmes, in those with AIDS and in those receiving immunosuppressive agents for inflammatory disorders, for example vasculitis. Among these patients, pneumonia is a leading cause of disease and death. The second part of the chapter deals specifically with an important opportunistic lung infection, *Pneumocystis carinii* pneumonia (PCP). Actinomycotic and fungal pneumonias are covered in Chapter 21, tuberculosis and opportunistic mycobacterial disease in Chapters 17–20 and bacterial and viral pneumonias in Chapter 13. Diseases that may mimic infection in the immunosuppressed are dealt with elsewhere: radiation pneumonitis in Chapter 13, cytotoxic and other drug-induced lung disease in Chapters 9 and 55, and lymphomas and Kaposi's sarcoma in Chapter 42. The minimally invasive procedures used in diagnosing lung disease in immunosuppressed patients are described in Chapter 8.

Pulmonary complications in the immunosuppressed may be due to infection with pathogenic organisms and opportunistic organisms of medium to low pathogenicity (Table 52.1) or to various non-infective complications (Table 52.2). These often have overlapping clinical and radiographic features, and pose diagnostic and therapeutic difficulties. Establishing a diagnosis, often by invasive

investigation, allows the use of specific and effective treatment, with the minimum of side-effects. This significantly improves survival [1].

An effective diagnostic approach requires knowledge of the potential pulmonary complications, a thorough approach to clinical assessment and a strategy for further investigation.

## Patterns of pulmonary complication

The type of immune disruption provides useful clues to the likely causes of infection (Table 52.1). However, the immunosuppression can be mixed in type in any patient and may vary with the stage of the underlying disease and treatment.

### Cancer chemotherapy programmes

Patients receiving vigorous cytotoxic chemotherapy for leukaemia and lymphoma have a high risk of fatal respiratory infection that threatens their survival, despite control of the malignancy.

Profound neutropenia during the early phases of treatment and consequent Gram-negative pneumonia is a special risk; fungal pneumonia (see Chapter 21), particularly that caused by *Aspergillus fumigatus*, is also possible if the neutropenia is severe and prolonged. Later in the course of the illness, T-lymphocyte immune deficiency develops and with it the special risk of PCP; before the introduction of specific chemoprophylaxis, this produced an attack rate of 18% annually in the childhood leukaemia population.

Non-infectious complications are various and include diffuse pneumonitis as a reaction to cytotoxic agents and the rare leucagglutinin reaction of the lung, in which diffuse radiographic change and hypoxaemia may follow white cell transfusion.

**Table 52.1** Opportunistic respiratory infection in the immunosuppressed.

Defect	Infections
Neutropenia, e.g. treated leukaemia	Bacteria: Gram-negatives, <i>Staphylococcus aureus</i> Fungi: <i>Aspergillus fumigatus</i> , <i>Mucor</i> spp.
Immunoglobulin deficiency, e.g. multiple myeloma, inherited defects	Encapsulated bacteria: <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i>
T-lymphocyte deficiency e.g. AIDS organ transplant recipients, treated malignancy	Fungi: <i>Pneumocystis carinii</i> , <i>Cryptococcus neoformans</i> Cytomegalovirus Mycobacteria: tuberculous and atypical Bacteria including <i>Legionella pneumophila</i> , <i>Nocardia asteroides</i>

**Table 52.2** Non-infectious complications in the immunosuppressed.

Pulmonary oedema
Pulmonary haemorrhage
Pulmonary embolism
Tumour (solid tumour, lymphoma/leukaemia, Kaposi's sarcoma)
Drug-induced pneumonitis
Radiation pneumonitis
Alveolar proteinosis
Leucagglutinin reaction

## Organ transplantation

### Renal

Bacterial pneumonias, particularly due to Gram-negative organisms including *Legionella* spp., may occur at any stage after transplantation [2,3]. Mycobacterial disease, especially tuberculosis, is a high risk for individuals with a past history of tuberculosis or likely exposure due to their country of origin. The disease often takes a rapid and disseminated pulmonary form.

Cytomegalovirus (CMV) pneumonia usually presents as a diffuse pneumonitis of mild to moderate severity at 4–6 weeks after transplantation. The most severe form occurs in patients with negative serology for CMV who receive a CMV-positive donor kidney [4].

Fungal infections are significant, particularly *P. carinii*; without chemoprophylaxis the attack rate for *Pneumocystis* in most centres is 10–12% annually [3]. The disease occurs typically from the onset of the second to the sixth month after transplantation, when immunosuppression is at its greatest, and presents with a rapidly progressive diffuse pneumonitis that is fatal unless specific treatment is initiated quickly. Other fungal pneumonias can be caused by *A. fumigatus*, *Mucor*, *Fusarium* and *Trichosporon* spp. and, in some parts of the world, by *Coccidioides* and *Histoplasma*.

Non-infectious complications are frequent and include pulmonary oedema (the result of impaired renal salt and

water excretion, cardiac dysfunction or fluid overload) and thromboembolism. Recurrence in the lung of the original renal-destroying disease may occur, as in Wegener's granulomatosis or Goodpasture's syndrome.

### Liver

The infective risks are similar to those for renal transplantation. Non-infectious complications include postoperative collapse and effusion, particularly at the right base, and also postoperative adult respiratory distress syndrome (ARDS).

### Heart/lung

The infective complications are similar to those listed for renal transplantation but there are also risks of disease due to *Nocardia asteroides* and the protozoan *Toxoplasma gondii*, both of which may be transmitted with the donor heart.

Non-infectious complications include collapse of the left lower lobe and paralysis of the left diaphragm, often due to cold injury of the phrenic nerve. Pulmonary oedema, due to heart failure or ARDS (post-pump syndrome), is not rare. A common late complication after lung transplantation is the development of obliterative bronchiolitis as a manifestation of organ rejection.

### Bone marrow transplantation

Profound neutropenia makes Gram-negative pneumonia a special risk [5]. CMV pneumonia, occurring at 6–12 weeks, is especially common; it is often progressive in this patient group and carries a high mortality despite initiation of treatment.

Non-infectious complications include early pulmonary oedema due to large-volume donations of intravenous fluid or to the cardiotoxicity of cytotoxic drugs. Common and important is an often fatal interstitial pneumonitis likely to be due to the direct pulmonary toxicity of the preparative irradiation and methotrexate therapy.

## AIDS

The current AIDS pandemic has had a major impact on respiratory medicine. The many pulmonary manifestations of HIV infection are discussed later in this chapter.

## Hypogammaglobulinaemia

Hypogammaglobulinaemia may be due to a variety of congenital and acquired causes and may be global or confined to subclass deficiency of IgA or IgG. Pulmonary complications can take the form of recurring bronchial infection, the development of bronchiectasis or bacterial pneumonias due to encapsulated *Streptococcus pneumoniae* or *Haemophilus influenzae*. Pneumococcal disease is especially common in the marked hypogammaglobulinaemia that accompanies multiple myeloma.

## Clinical features of lung disease

Thorough clinical and radiographic review is essential, and needs to take account of the various potential infectious and non-infectious pulmonary problems and the clues that arise from the history, examination, review of fluid charts, drug schedules and chest radiology. In many instances, the respiratory illness may simply be an episode of acute bronchitis; cough and purulent sputum follow a coryzal illness and there is little constitutional disturbance and no clinical or radiographic signs of pulmonary consolidation. The more important clinical problem is the patient with breathlessness or radiographic consolidation accompanied by fever, for whom the differential diagnosis is broad and includes non-infectious disease. Fever itself, particularly when it is high and associated with chills, suggests infection though some non-infectious conditions such as drug reactions may also cause this.

The patient's background provides useful pointers in the differential diagnosis. Gram-negative sepsis and fungal disease are particular risks in the profound neutropenia seen in the early vigorous treatment of leukaemias and lymphomas, while PCP is a possibility at a later stage; CMV complicates organ transplantation usually at about 2 months and may be severe and fatal in bone marrow transplantation, whereas it is relatively milder after renal transplantation. Geographical factors may be relevant: infection with fungal disease such as coccidioidomycosis or histoplasmosis occurs in the Americas, while disseminated strongyloidiasis is seen in patients particularly from the West Indies and Far East. Tuberculosis may be reactivated in patients from developing countries but especially the Indian subcontinent and South-East Asia. The disease may disseminate and progress more rapidly in the immunosuppressed.

Physical examination needs to be comprehensive and should include a search for tumour or bleeding at extra-

pulmonary sites. Skin disease may be present in graft-versus-host disease and cutaneous lesions may provide diagnostic clues of systemic vasculitis. Signs of intracerebral infection are a principal feature of cryptococcal disease and may complicate aspergillar and nocardial infections. Arthropathy and biochemical evidence of hepatitis occur frequently in CMV disease. Haemoptysis may be part of an infective syndrome but raises the possibility of pulmonary embolism or haemorrhage. Pleurisy with pleural pain and pleural rub is neither a feature of infection with *Pneumocystis* nor of cardiogenic pulmonary oedema or alveolar haemorrhage. In PCP, fever and breathlessness may precede definite radiographic changes; absence of auscultatory physical signs in the chest is characteristic.

## Radiology and lung sampling

The plain chest radiograph usually provides definitive evidence of the presence, extent, distribution and character of pulmonary consolidation, and the presence or absence of other features including those of cardiac failure (cardiomegaly, pulmonary venous congestion and Kerley B lines) or pleural disease. The lateral chest radiograph is valuable in localizing lesions for further investigation by bronchoscopy. Focal radiographic abnormalities are more likely to be infective than non-infective and are also more likely to be due to bacterial than opportunistic organisms. A retrospective review of the aetiology of episodes of pulmonary infiltration in 139 patients with leukaemia showed that in those with focal radiographic abnormalities, 74% of infiltrates were infective and, of these, 87% were bacterial and only 13% opportunistic [6]. On the other hand, 65% of diffuse infiltrates were non-infective but of the remaining 45% that were infective, the great majority (93%) were opportunistic.

CT may provide more detailed information, including anatomical information for targeting of sampling procedures. However, there are few microbe-specific radiographic changes, for instance the radiographic features of *Pneumocystis*, mycobacterial and CMV infection can be very similar. However, confluent segmental or lobar consolidation accompanying an acute clinical illness (<48 h) strongly suggests bacterial pneumonia.

Sputum, if expectorated, provides a valuable sample for preliminary microbiological assessment by Gram staining and culture. Sputum may be induced by the inhalation of nebulized hypertonic (2.7%) saline [7]; such samples have proved useful in the diagnosis of PCP (see below) in AIDS subjects, although precautions are needed to protect other patients from the dissemination of microorganisms in this process.

Blood cultures should be taken in all patients in whom sepsis is a possibility and may give a positive yield in up to one-third of such cases [8], although it is probable that

appropriate antimicrobial therapy has been initiated on empirical grounds in advance of the result.

Open lung biopsy (see Chapter 8) provides the best sample of pulmonary tissue but may precipitate the need for assisted ventilation or be complicated by pneumothorax or wound sepsis. Percutaneous lung biopsy or fine-needle aspiration (see Chapter 8) carries risks of bleeding or pneumothorax (proportional to the calibre of the needle) but is very useful in sampling peripheral nodules. Fibreoptic bronchoscopy (see Chapter 8), with bronchoalveolar lavage (BAL) and with or without transbronchial biopsy, is now widely used for investigating pneumonitis in the immunosuppressed and can produce diagnostic rates of 50–80% [9–12]. BAL provides a good specimen for microbiological assessment using staining, monoclonal antibodies and DNA probes, and culture; cytological examination of the fluid may diagnose pulmonary haemorrhage and malignant infiltrates. BAL rarely produces bleeding or pneumothorax. It does not provide definitive information on drug-induced lung disease or other non-infective alveolitis, which need biopsy of tissue for histology.

In all these samplings, the application of molecular techniques such as DNA amplification is improving the rapidity and sensitivity of screening for organisms such as *P. carinii* and *Mycobacterium tuberculosis* [13,14].

## Practical approach to diagnosis

Episodes of bronchitis are typified by prominent cough producing purulent sputum but no clinical or radiographic evidence of consolidation. After sputum has been obtained for study, these episodes should be treated with an antibiotic effective against the likely pathogens, *H. influenzae* and *Strep. pneumoniae*. There are  $\beta$ -lactamase-producing strains of *H. influenzae* (20% of isolates in the UK currently), although treatment with oral co-amoxiclav or doxycycline is usually effective.

A pneumonia of abrupt onset and progress, with accompanying segmental or lobar radiographic shadowing, strongly suggests bacterial infection. Antibiotic treatment should be started promptly after swift and simple microbiological investigation based on blood, urine, natural or induced sputum and, if available, pleural fluid samplings. A regimen that provides broad antibacterial activity, i.e. covering *Strep. pneumoniae*, *H. influenzae*, *Staphylococcus aureus* and many Gram-negative organisms, should be given intravenously. One suitable combination is an antipseudomonal penicillin with a  $\beta$ -lactamase inhibitor and gentamicin. The possibility of infection by *Legionella* spp. (see Chapter 13) should be considered and may be covered with a macrolide [15].

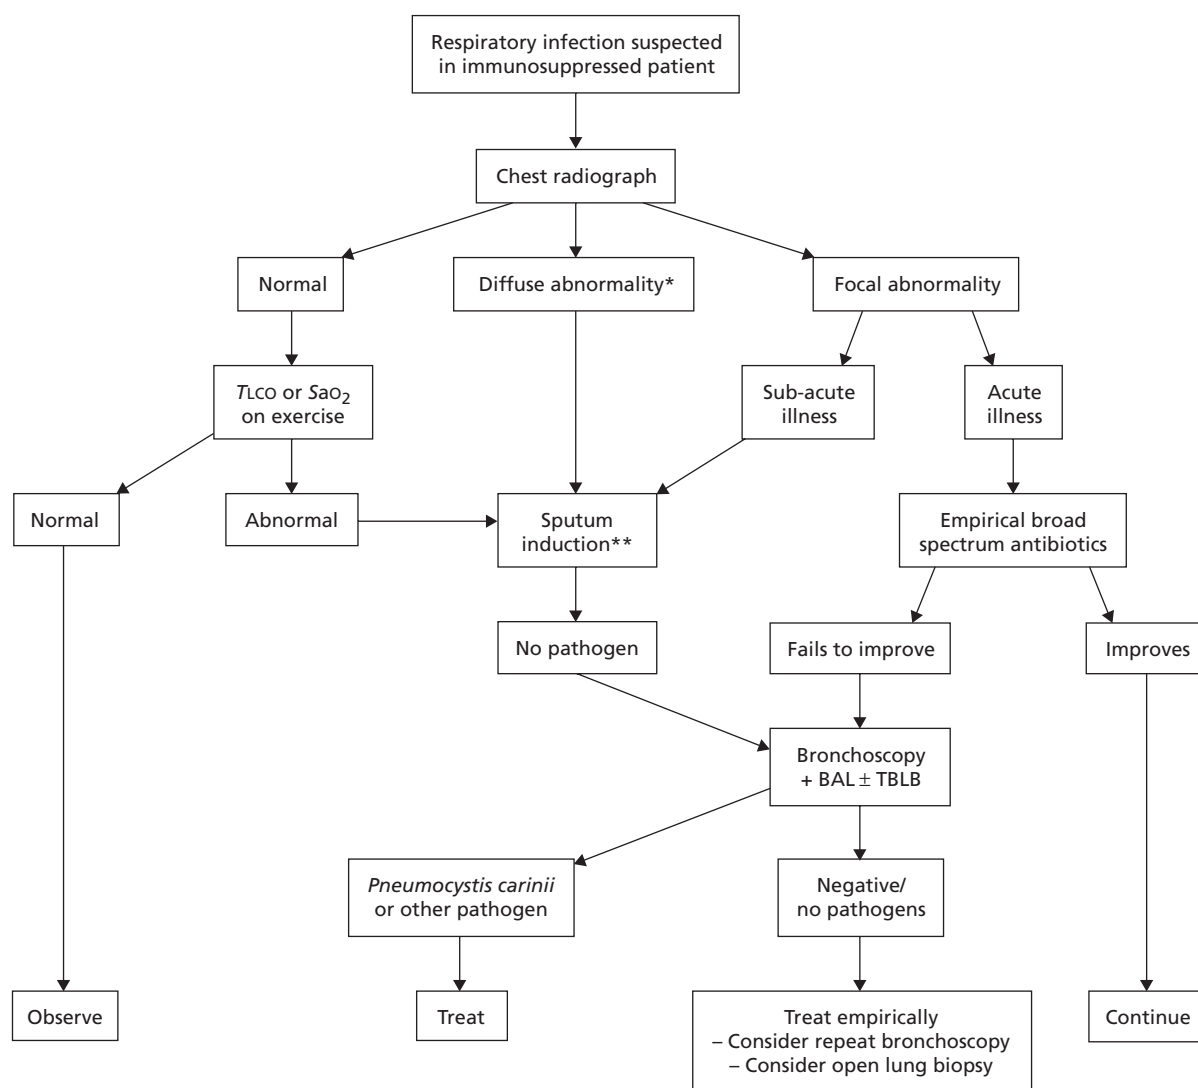

When the pace of the illness is less acute or when the chest radiograph shows more diffuse or scattered change, the differential diagnosis enlarges. First, sputum or

induced sputum should be examined by microscopy using both Gram stain and appropriate techniques for *P. carinii* (see below) and mycobacteria; the sample should also be cultured. If this does not provide a prompt diagnosis, a decision needs to be made about further diagnostic techniques. Percutaneous fine-needle aspiration for cytology and microbiology is most applicable in the case of peripherally placed nodules. For infiltrative or pneumonic radiographic changes when infection is primarily suspected, fibreoptic bronchoscopy with BAL is appropriate. If there is suspicion of autoimmune or drug-induced alveolitis, transbronchial lung biopsies can also be taken at bronchoscopy (see Chapter 8). The procedure can be completed in 15 min and be performed in hypoxaemic patients using local anaesthesia with concurrent oxygen supplementation. Chest radiographs allow localization of the pneumonia and the accurate direction of the flexible bronchoscope to a bronchus subtending the site. In diffuse disease, the middle lobe may be chosen and the bronchoscope is impacted firmly there. Three or four 50-mL aliquots of sterile saline are instilled singly and 30–60% of the fluid recovered by suction into a trap. Some of this sample is centrifuged and slides made from the deposit for diagnostic microscopy. The remainder is used for culture. Semi-quantitative techniques improve accuracy in diagnosing bacterial disease. The use of monoclonal antibodies facilitates the counting of CMV-‘positive’ alveolar macrophages. Immunofluorescent staining with conjugated *P. carinii* monoclonal antibodies also demonstrates brightly stained cysts and is a very useful microbiological search technique. Grocott–Gomori methenamine silver staining of BAL fluid for *P. carinii* has been shown on correlative postmortem studies to have sensitivity and specificity approaching 100%. Mycobacteria are more efficiently screened using fluorescent microscopy with auramine stains rather than by the Ziehl–Nielsen method. Giemsa stains are used to assess haemorrhage or malignant infiltration. *Legionella* may be identified in secretions by direct immunofluorescent antibody testing. Many of these foregoing results should be available within 4 h and simple cultures within 36 h.

If the procedure provides no diagnosis in a patient who is in a declining state, then open lung biopsy offers definitive sampling. Open lung biopsy is the only technique that gives totally reliable information on alveolitis of non-infective origin. Pulmonary capillary wedge pressure measurements, pulmonary angiography and ventilation–perfusion lung scanning may be required to establish the diagnosis of pulmonary oedema or embolism. A diagnostic algorithm is presented in Fig. 52.1.

## Treatment

With the exception of acute-onset lobar pneumonia, antimicrobial therapy is best started when a specific diag-

**Fig. 52.1** Algorithm for the management of an immunosuppressed patient in whom respiratory infection is suspected. \*, If suspicion of *Pneumocystis* pneumonia is high, start treatment at this point. \*\*, If mycobacterial or *Pneumocystis* pneumonia is suspected and patient is unable to expectorate. BAL, bronchoalveolar lavage; TBLB, transbronchial lung biopsies.

nosis has been made. In PCP, the first-line treatment is still high-dose co-trimoxazole or pentamidine [16] as described later in this chapter. In the AIDS population, the rate of side-effects of these agents is high and reactions that include fever, rash and renal impairment often demand change of therapy to the alternative agent or to other agents, including trimetrexate-folate or dapsone-trimethoprim, in order to allow the necessary 3 weeks of treatment to be completed. There is little evidence that changing regimens because of failure of the pneumonia to respond is useful, although there are data supporting the

coadministration of corticosteroids particularly in AIDS (see below).

Despite the severity of the disease, recovery is frequently seen in aspergillar pneumonia treated vigorously with amphotericin [17,18]; the side-effects of this agent may be limited by formulation of the drug with liposomes or lipid emulsion (see Chapter 9).

The standard chemotherapeutic regimens should be used for tuberculosis, though increasing rates of drug resistance to agents that include isoniazid and rifampicin are being documented in cities in the USA [19].

CMV pneumonia is most effectively treated with the guanine analogue ganciclovir (see Chapter 9); the addition of intravenous immunoglobulin should be considered in severe disease [20,21].

Often the severe hypoxaemia accompanying many of these pneumonias may demand a period of mechanical ventilation, high concentrations of inspired oxygen and the use of positive end-expiratory pressure. Previously, the outlook for AIDS patients with disease of such severity

was grim so in appropriate circumstances humane terminal care was often more appropriate for this group [22]. In recent years, with the advent of highly active antiretroviral therapy, patients can attain sustained good health even after such a life-threatening illness.

In transplant patients and oncology patients still receiving immunosuppressive chemotherapy, there may be need to taper the dosage of such agents to allow recovery from pneumonia. Neutropenic patients (including those with HIV infection) benefit from adjuvant treatment with granulocyte colony-stimulating factor.

## Prevention

Prevention of PCP depends upon chemoprophylaxis with either thrice-weekly oral co-trimoxazole or monthly inhaled pentamidine [16,23]. Such prophylaxis is a routine part of leukaemia chemotherapy in childhood, organ transplantation schedules and the management of AIDS patients, provided the agent can be tolerated (see below).

Chemoprophylaxis is also important in the prevention of tuberculosis. Daily oral isoniazid over 1 year can be used at the initiation of immunosuppressive chemotherapy, for example in the transplant group, if there is a past history of tuberculosis or if the patient is from a geographical location where the disease is prevalent. CMV disease is most severe in transplant patients who are seronegative and who receive seropositive blood products or transplant. Avoidance of a positive organ is advised if possible, although many centres now administer live attenuated CMV vaccine to CMV-seronegative potential transplant recipients since it offers protection against disease of moderate to high severity [24].

The risk of any opportunistic pneumonia is increased by the number and dosage of immunosuppressant agents. Clinicians and investigators should try to define the lowest dosages of such agents that achieve the goals of suppressing inflammatory vasculitis, maintaining an organ transplant or eradicating treatable tumour.

## HIV and AIDS

AIDS was first recognized in 1981 following clusters of PCP in young gay and drug-using men in California and New York [25,26]. Since that time pulmonary infections have accounted for much of the morbidity and mortality related to this infection. About 70% of patients with HIV infection experience a pulmonary complication during life [27], and additional pulmonary pathology (particularly pneumonia, tuberculosis and pulmonary embolism) is an often unexpected finding at autopsy [28]. Worldwide, it is estimated that 30.6 million patients are living with HIV and 90% of these are in developing countries [29]. The burden of HIV-related pulmonary disease in developing countries is therefore immense.

The nature of the pulmonary complications of HIV reflect level of immunodeficiency, socioeconomic status, lifestyle, country of residence and access to prophylactic and HIV disease-modifying therapies. For the fortunate few in developed countries, HIV disease-modifying drugs dramatically alter the natural history and hence pulmonary complications of the disease (see below). The great cost of antiretroviral therapy (estimated at \$US12 000 per person per annum) makes therapy unfeasible for those dependent on state healthcare in developing countries.

The three most important and common pulmonary complications of HIV are tuberculosis, PCP and bacterial pneumonia, these comprise greater than 90% of pulmonary complications worldwide. The incidence of PCP in developed countries has markedly declined since the introduction of effective prophylaxis with co-trimoxazole and HIV disease-modifying therapy. In developing countries, bacterial infections (including *M. tuberculosis* and *Strep. pneumoniae*) are of much greater importance, perhaps because these virulent infections occur at an earlier stage in the disease before the profound immunosuppression required for PCP.

Although most of the pulmonary complications of HIV infection are not unique to the disease, the variability and non-specificity of clinical and radiological findings in these patients frequently complicate their diagnosis.

## HIV and lung defences

HIV-infected patients with respiratory symptoms frequently have detectable HIV in BAL fluid, even in the absence of opportunistic infections or tumours [30]. The lung may become diseased via pro-monocytes infected in the bone marrow that subsequently migrate and then mature into alveolar macrophages. Alternatively, free virus may be transported to the lungs via the pulmonary circulation [31]. The nature of the deficiencies in pulmonary host defences to infection in patients infected with HIV is complex and largely extrapolated from studies of circulating immune cells. HIV infection is characterized by an acquired depletion of circulating CD4<sup>+</sup> lymphocytes whose primary role is in the regulation of cell-mediated immunity. CD4<sup>+</sup> lymphocytes recognize antigens presented by accessory cells, regulate the expansion and differentiation of antibodies (B lymphocytes) and regulate the development of macrophages and other cytotoxic cells. HIV is directly cytopathic to CD4<sup>+</sup> lymphocytes but also leads to qualitative defects in surviving cells, including functional defects in response to soluble mitogens, reduced recall proliferation to previously encountered antigens, defective interleukin 2 production and reduced production of interferon  $\gamma$  in response to antigen. Such defects in cell-mediated immunity lead to increased susceptibility to viral, fungal and protozoal infections.

Antibody production is also critically dependent on activation of B lymphocytes by CD4<sup>+</sup> lymphocytes, so humoral defects in immunity such as recurrent serious bacterial infections are common. Natural killer cells, which are important in host defence against infection and tumour surveillance, may be non-functional in HIV infection as they require signals from CD4<sup>+</sup> lymphocytes for optimal function. BAL fluid in patients with AIDS generally shows increased numbers of lymphocytes in comparison with HIV-negative patients; however, the numbers of CD4<sup>+</sup> cells are markedly reduced and CD8<sup>+</sup> lymphocytes (which are cytotoxic to HIV-infected cells) are increased. Non-specific interstitial pneumonitis (found in about half of asymptomatic HIV-infected adults) and lymphocytic interstitial pneumonitis (found in about half of HIV-infected children with pulmonary disease) are characterized by pulmonary infiltration with CD8<sup>+</sup> lymphocytes (see later). The conditions differ histologically but it is thought that they both occur as a result of an immunological response of CD8<sup>+</sup> cells to HIV-infected cells in the lungs.

In addition to the changes described in T-cell lymphocytes, there are also disturbances in the numbers and function of a wide variety of other cell types. In particular, alveolar macrophages (which express the CD4 receptor and are directly infected by HIV) show decreased chemotaxis, which may account for the reduced granulomatous reaction seen in mycobacterial disease. Defects in phagocytosis, intracellular killing and antigen presentation have also been described.

### Differential diagnosis in HIV-infected patients with pulmonary disease

The pulmonary complications of HIV infection can be broadly classified as infectious or non-infectious (Table 52.3). For the physician presented with an HIV-infected patient with respiratory symptoms, the clinical history can give important clues as to the nature of the pulmonary disease (Table 52.4). Respiratory symptoms and signs may be less rewarding in determining the aetiology of pulmonary involvement, although general physical examination is more helpful. Radiological signs are highly variable and may mask dual pathology (Table 52.5).

Formal staging of HIV infection is of some help in guiding a differential diagnosis and is also an important epidemiological tool. The Centers for Disease Control and Prevention in the USA published a revised classification system for HIV infection in 1993 (Table 52.6), which takes into account the CD4<sup>+</sup> lymphocyte count as well as the occurrence of opportunistic infections; this system is now widely adopted and more usefully reflects disease progression than previous definitions [32]. In developing countries, where radiological and laboratory facilities may be limited, these definitions can be adapted [33].

**Table 52.3** Infectious and non-infectious respiratory tract complications of patients with HIV infection.

\* Some 'non-infectious' complications are associated with infectious agents (see text).

### Patients with primary HIV infection

An acute seroconversion illness occurs in upwards of half of those infected with HIV within the first few weeks of exposure (sexual or parenteral). This is manifested by a mononucleosis-type syndrome, with fever, rash, myalgia, lymphadenopathy and sore throat. It may be associated with high circulating levels of virus and can lead to a precipitous but short-lived depression of cell-mediated immunity, manifested by a low CD4<sup>+</sup> lymphocyte count. At this time a minority of patients may develop PCP or bacterial pneumonia as well as a variety of neurological conditions and oesophageal candidiasis.

**Table 52.4** Clinical evaluation of a patient with HIV infection and respiratory disease.

Risk factor	Pulmonary disease
Nationality and travel history	Tuberculosis, endemic mycoses
Use of prophylaxis for PCP, MAI	Reduce risk of PCP, MAI and other bacteria
Past and present antiretroviral use and compliance	Reduces risk of opportunistic infections and Kaposi's sarcoma
Intravenous drug misuse	Bacterial infection, <i>Rhodococcus</i> , tuberculosis, pulmonary embolic and granulomatous disease
Sexuality	Kaposi's sarcoma, cytomegalovirus in gay men
Smoking history	Bacterial infection, <i>Legionella</i>
Social deprivation	Tuberculosis
Prior respiratory disease	Consider in differential diagnosis
Occupation	Exposure to airborne particles/agents Farms ( <i>Rhodococcus</i> )
Pets	Cats (toxoplasmosis) Pigeons (cryptococcosis)
Undercooked meat	Toxoplasmosis
CD4 <sup>+</sup> T-lymphocyte count*	
< 0.5 × 10 <sup>9</sup> /L	Tuberculosis in selected groups (above), bacterial infection
< 0.2 × 10 <sup>9</sup> /L	PCP
< 0.1 × 10 <sup>9</sup> /L	Kaposi's sarcoma, MAI, cytomegalovirus, non-Hodgkin's lymphoma
HIV RNA viral load > 30 000/mL	Increased risk of progression to opportunistic infections
Low neutrophil count	Aspergillosis, candidosis, Gram-negatives

\* These CD4<sup>+</sup> counts are offered as a guide only. Opportunistic infections may occur outwith these ranges.

PCP, *Pneumocystis carinii* pneumonia; MAI, *Mycobacterium avium-intracellulare*.

**Table 52.5** Chest radiograph findings in patients with HIV infection.

Chest radiograph	Diagnosis
Normal	No pulmonary disease Bronchitis <i>Pneumocystis carinii</i> pneumonia
Focal infiltrate(s) (may cavitate)	Bacterial pneumonia Tuberculosis and other mycobacteria <i>Pneumocystis carinii</i> pneumonia Cryptococcosis and other mycoses Adenocarcinoma Kaposi's sarcoma
Pleural effusion	Bacterial pneumonia Tuberculosis and other mycobacteria Kaposi's sarcoma Adenocarcinoma
Mediastinal adenopathy	Tuberculosis and other mycobacteria Non-Hodgkin's lymphoma Kaposi's sarcoma
Interstitial infiltrate (may have focal nodularity)	<i>Pneumocystis carinii</i> pneumonia Bacterial pneumonia Tuberculosis and other mycobacteria Lymphocytic interstitial pneumonitis Non-specific pneumonitis Cytomegalovirus pneumonitis

### Progressive immunosuppression

The spectrum of respiratory disease changes as immunodeficiency develops. In the patient with a normal CD4<sup>+</sup> lymphocyte count and undetectable or low HIV RNA in blood (<10 000 copies/mL), the risks of opportunistic infection are low. Lower respiratory tract infections are no more common than in the normal population at this early stage, although there is increased reporting of upper respiratory tract infections. This may simply reflect increased surveillance in the HIV-infected population. Intravenous drug misusers who are infected with HIV run the risk of endocarditis, septic pulmonary emboli and talc (magnesium trisilicate) embolism with subsequent granulomatous reactions [34].

As one might expect, more virulent organisms cause problems earlier in the natural history of HIV infection. Bacterial pathogens such as *Strep. pneumoniae* and *H. influenzae* are important at CD4<sup>+</sup> counts of less than 0.5 × 10<sup>9</sup>/L in both developing [35] and developed [36] worlds. In areas of endemicity, tuberculosis also occurs at relatively preserved CD4<sup>+</sup> counts and tends to dominate the burden of HIV-related ill-health [37,38]. Such high-virulence infections, when occurring early in the course of HIV infection, present in a similar fashion to disease

**Table 52.6** Revised classification system for HIV infection and expanded AIDS surveillance case definition for adolescents and adults, 1993.

CD4 <sup>+</sup> T-cell count	Clinical categories		
	A: asymptomatic, acute (primary) HIV or PGL	B: symptomatic, not A or C conditions	C: AIDS-indicator conditions*
1 $\geq 0.5 \times 10^9/L$	A1	B1	C1
2 $0.2\text{--}0.499 \times 10^9/L$	A2	B2	C2
3 $< 0.2 \times 10^9/L$ AIDS-indicator T-cell count	A3	B3	C3

\* AIDS-defining conditions are shown in Table 52.7.  
PGL, persistent generalized lymphadenopathy.  
Categories A3, B3 and C1–C3 are included in the AIDS case definition.

in immunocompetent HIV-negative patients. Tuberculosis presenting in advanced immunosuppression can be more cryptic and is more frequently extrapulmonary than in HIV-negative patients (Figs 52.2–52.4). Although PCP does occur in developing countries it is infrequently isolated (when facilities for its detection are available), presumably because it is a true opportunist and does not occur at the level of immunosuppression that predisposes patients to bacterial and tuberculous infections [39].

Opportunistic infections that occur later in HIV infection depend on the endemic infections of the patient's

country of past and present residence, for example cryptococcosis is rare in cold climates, tuberculosis is common in developing countries and deprived social groups, histoplasmosis is common in the Americas and toxoplasmosis is more common in Africa. Pulmonary complications may also be suggested by other systemic features of the disease (Table 52.7). Examples include characteristic skin and mucosal lesions in Kaposi's sarcoma, meningoencephalitis in cryptococcosis, cerebral mass lesions in toxoplasmosis, oral/pharyngeal thrush in patients with pulmonary candidiasis, and retinitis with CMV pneumonitis. In such

conditions the pulmonary manifestations may be of secondary importance. It should be remembered that it is common for patients with HIV infection to have concurrent infections or malignancy.

### Selected pulmonary conditions associated with HIV infection

The reader is referred to other sections of this book for detailed descriptions of pneumonia (Chapter 13), tuberculosis (Chapters 16–19), lung tumours (Chapters 41 & 42) and interstitial lung disease (Chapters 31, 40 & 51). PCP is described separately in this chapter. This section outlines some of the peculiarities of less well-known or well-recognized pulmonary complications and is not meant as an exhaustive description of pulmonary disease in HIV infection.

### Infectious complications

#### *Mycobacterium tuberculosis*

As mentioned above, tuberculosis presenting later in HIV infection may show atypical radiographic features. Infiltrates may be present in any part of the lung and node

enlargement is common, as is miliary dissemination. The presence of hilar and mediastinal node enlargement often provides the diagnostic clue.

#### *Mycobacterium avium-intracellulare*

Infection with this and other non-tuberculous mycobacteria usually occurs when the CD4<sup>+</sup> lymphocyte count is below  $0.1 \times 10^9/L$ . These organisms are ubiquitous in nature and may colonize the respiratory or gastrointestinal tracts. Up to 40% of patients with advanced HIV infection develop disseminated disease. Typically, patients present with fever, night sweats, weight loss, anaemia, diarrhoea and abnormal liver function tests. Pulmonary disease without dissemination is uncommon in patients with HIV infection, although cavitating lung infiltrates are well recognized [40]. A wide range of radiological appearances may be seen (Figs 52.5 & 52.6). Non-tuberculous mycobacteria in sputa must be differentiated from the morphologically similar *M. tuberculosis* since the atypicals are frequently colonizers of the respiratory tract. *M. avium-intracellulare* is resistant to first-line antituberculous therapy but like tuberculosis requires combination therapy with at least three active drugs. Prognosis is poor following the diagnosis of disseminated infection with *M. avium-intracellulare* and drug therapy is often poorly tolerated (see Chapter 20).

#### *Rhodococcus equi*

This facultative, intracellular, coccobacillary organism is a soil saprophyte and a common pulmonary pathogen of farm animals and occasional opportunist in humans. It is a well-described but infrequently recognized cause of acute or insidious pulmonary infections (often cavitating pneumonia), bacteraemia and disseminated disease in patients with advanced HIV infection (CD4<sup>+</sup> count  $< 0.1 \times 10^9/L$ ). When isolated, *R. equi* is often found with other pulmonary pathogens and, without careful consideration, may be dismissed as a diphtheroid. Infection is most frequently described in intravenous drug misusers and is often associated with exposure to farm animals [41]. Therapy for *R. equi* infection requires months of combination antimicrobial therapy because the organism persists and multiplies within macrophages. *In vitro* the organism is sensitive to ciprofloxacin, gentamicin, glycopeptides, erythromycin, rifampicin, tetracyclines and co-trimoxazole. Some patients who have responded poorly to antibiotics have been managed with surgical resection.

#### *Herpesvirus*

HIV infection is characterized by infections with the herpes group of viruses [42]. Complications are usually manifest in extrapulmonary sites. The most important of

**Fig. 52.5** Cavities in area of consolidation in left mid zone of patient with AIDS. Postmortem culture showed this to be due to *Mycobacterium avium-intracellulare*. (Courtesy of Dr Diana Buchanan.)

**Fig. 52.6** Bilateral lower zone consolidation and superior mediastinal node enlargement in patient who died of disseminated *Mycobacterium avium-intracellulare* infection. (Courtesy of Dr Diana Buchanan.)

the herpes group is CMV infection, which occurs in 100% of gay men with HIV infection and to a lesser extent in other risk groups. Disease usually occurs after significant immunosuppression ( $CD4^+$  count  $<0.1 \times 10^9/L$ ). The most common manifestation of CMV disease is retinitis,

although the lungs, adrenals, central nervous system, liver and colon may also be involved. Pneumonitis may be sub-clinical but occasionally causes respiratory failure. Most cases occur with other opportunistic pathogens like PCP, and it is often difficult to fully gauge the importance of

**Fig. 52.7** Diffuse bilateral shadowing in AIDS patient who failed to respond to treatment for *Pneumocystis* pneumonia; biopsy confirmed cytomegalovirus. (Courtesy of Dr Diana Buchanan.)

CMV in such situations (Fig. 52.7). Rapid fulminant disease, which characteristically occurs in patients following bone marrow transplantation, is unusual in HIV-infected patients. Diagnosis is via BAL or sputum induction, which reveals typical inclusion bodies in smears fixed with Giemsa or haematoxylin–eosin in 20–30% of cases. Sensitivity may be improved by using CMV-specific DNA probes or monoclonal antibodies. However, it should be remembered that CMV causes a subclinical infection of the salivary glands and so can be isolated in respiratory secretions in the absence of pneumonitis. Treatment with the nucleoside analogues ganciclovir, foscarnet or cidofovir should be considered in symptomatic patients if there is documented CMV pulmonary involvement in the absence of other pathogens. Alternatively, treatment should be considered in patients with other copathogens if they are deteriorating clinically despite optimal therapy for the other organisms.

Herpes simplex virus (HSV) and varicella zoster virus (VZV) pneumonitis have both been described in HIV infection but probably occur less commonly than CMV pneumonitis. VZV pneumonitis is a particularly severe complication of HIV infection in children and is usually accompanied by the vesicular rash. Shingles is not usually accompanied by pneumonitis in adults. The diagnosis of HSV by virus culture and histopathology may be compli-

cated by virus shedding from cold sores. Treatment in both VZV and HSV is effective with intravenous aciclovir.

Kaposi's sarcoma is now believed to arise as a result of infection with a newly described virus, human herpes virus 8 [43]. Pulmonary involvement is usually accompanied by skin and mucosal lesions but has been described in isolation. The radiographic appearances are highly variable (Table 52.5, Figs 52.8 & 52.9) but endobronchial lesions, which are red or purple, are often present in parenchymal disease. The lesions are highly vascular so biopsy should be avoided (Fig. 52.10). The clinical course of pulmonary disease is also variable. Therapy with cytotoxic chemotherapy has been relatively unsuccessful and palliative radiotherapy is often required for bleeding or obstructing lesions. More recently, regression of pulmonary and cutaneous lesions has been demonstrated following highly active antiretroviral chemotherapy (see below) [44].

### Non-infectious complications

#### *Non-Hodgkin's lymphoma*

In some cases B-cell tumours are related to prior Epstein–Barr virus infection. Patients with HIV-related non-Hodgkin's lymphoma present with symptoms of

**Fig. 52.8** Chest film of AIDS patient showing multiple nodules of Kaposi's sarcoma. (Courtesy of Dr Diana Buchanan.)

**Fig. 52.9** Cavitating consolidation in left mid zone of AIDS patient with intrapulmonary Kaposi's sarcoma. (Courtesy of Dr Diana Buchanan.)

**Fig. 52.10** Kaposi's sarcoma of bronchus showing epithelium to right with underlying slit-like vascular spaces lined by prominent endothelial cells (haematoxylin & eosin  $\times 250$ ). (Courtesy of Dr Nick Francis.)

night sweats, fever and weight loss, usually when CD4<sup>+</sup> counts are less than  $0.1 \times 10^9/L$ . Disease is often extranodal and although patients may have an enlarging mass on a chest radiograph, many other radiographic signs may be present. Transbronchial biopsies are often not successful in obtaining diagnostic tissue, which usually requires more invasive measures. Prognosis following a diagnosis of non-Hodgkin's lymphoma is extremely poor.

#### *Interstitial pneumonitis*

This is a group of histologically well-defined pulmonary complications whose aetiology and clinical significance is currently uncertain [45–47]. Lymphocytic interstitial pneumonitis occurs frequently in children infected with HIV but is only occasionally seen in adults (usually Afro-Caribbeans). It is also associated with other autoimmune disorders such as Sjögren's syndrome and chronic active hepatitis. Lymphocytic interstitial pneumonitis is thought to occur as a result of an immunological reaction to HIV or Epstein-Barr virus within the lung and is classified as a lymphoproliferative disorder by some. Symptoms and signs are non-specific in HIV infection but patients usually develop progressive dyspnoea. Symptoms may resolve spontaneously or progress to respiratory failure. Diagnosis depends on histology and exclusion of opportunistic infections. Lung biopsy reveals firm grey nodules characterized by a lymphocytic infiltrate. Although granulomas are not present, the infiltrate can take on a follicular appearance with germinal centres. Antiretroviral therapy may help and corticosteroids have been used in patients without HIV infection.

Non-specific interstitial pneumonitis is well described in adults with HIV infection and is characterized by an interstitial inflammatory infiltrate with a predominance of

lymphocytes and plasma cells. In contrast to lymphocytic interstitial pneumonitis, a follicular pattern with germinal centres is not seen. The aetiology is not known but it may occur as a result of previous opportunistic infections or, like lymphocytic interstitial pneumonitis, as an immune response to HIV in the lung. There are no specific clinical features that distinguish non-specific interstitial pneumonitis from other more common pulmonary disorders, although symptoms are usually mild and the condition may resolve or stabilize spontaneously.

Bronchiolitis obliterans organizing pneumonia has been described in patients infected with HIV. Its mode of presentation is similar to the condition in HIV-negative patients and there is no evidence to suggest that it occurs more frequently in the HIV-infected population [48].

#### *Pulmonary hypertension*

Pulmonary hypertension is estimated to occur in 1 in 200 patients with HIV infection. It does not correlate with the stage of HIV infection or with the occurrence of opportunistic infections. Compared to patients with primary pulmonary hypertension, patients with HIV-related pulmonary hypertension are younger, less dyspnoeic and have lower peak pulmonary artery pressures. The pathological findings are usually of plexogenic pulmonary arteriopathy, although less frequently the thrombotic-fibrotic variant occurs. It is believed that HIV infection is the cause, perhaps through release of epidermal growth factors, induction of nitric oxide synthase and subsequent increased vessel tone and endothelial proliferation [49]. Secondary causes of pulmonary hypertension in patients with HIV include obstructive talc granulomas within small pulmonary arteries in intravenous drug users and pulmonary hypertension associated with chronic liver

disease and portal hypertension (e.g. induced by hepatitis C virus). In addition, pulmonary thromboembolic disease is often an unexpected finding in autopsies in patients with HIV infection.

### **Primary lung tumours**

Primary lung tumours are weakly associated with HIV infection. A recent large-scale survey of 98336 patients with HIV infection and a large cancer register in the USA estimated a relative risk of lung adenocarcinoma of 2.5 (95% confidence interval 1–5.1). Other tumours, such as Kaposi's sarcoma, non-Hodgkin's lymphoma, Hodgkin's lymphoma, multiple myeloma, brain tumours and seminomas, were unequivocally associated with HIV infection [50].

### **Prevention of HIV-related pulmonary disease**

The 1990s has seen an explosion in the development of new antiretroviral agents that have revolutionized the management of HIV infection. Initial pessimism following the poor success of monotherapy with the nucleoside analogue zidovudine [51] has been replaced with optimism as dual and triple drug regimens have shown at least short-term promise [52]. Highly active antiretroviral therapy is a combination of an HIV-protease inhibitor and two nucleoside reverse transcriptase inhibitors and is the standard care for many patients in developed countries. The nucleoside reverse transcriptase inhibitors (zidovudine, lamivudine, didanosine, zalcitabine, stavudine) are phosphorylated by thymidine kinase and then bind preferentially to retroviral reverse transcriptase. Proviral DNA formation is blocked because the drug is incorporated into the viral DNA with resultant 'misreading' and chain termination. The protease inhibitors inhibit post-translational processing of the polyprotein products of *gag* and *gag-pol* genes into the functional core proteins and viral enzymes, leading to release of immature non-infectious virus [53].

Outside clinical trials in countries where such therapy is freely available, AIDS-related mortality has dramatically declined [54]. In addition, the rate of progression to an AIDS diagnosis (particularly PCP) has been reduced [55]. Guidelines in HIV therapy are evolving as trial data emerge and experience with newer agents such as the non-nucleoside reverse transcriptase inhibitors improves [56].

Long-term compliance with complex drug regimens with large side-effect profiles may be difficult for many patients. The protease inhibitors are associated with a growing number of metabolic disturbances, including renal stones, diabetes mellitus, body fat redistribution and abnormalities in lipid metabolism [57]. In addition, cryptic mycobacterial and CMV infection may flare up during ini-

tiation of highly active antiretroviral therapy, presumably due to immune reconstitution. There is good evidence that viral resistance, leading to renewed risk of opportunistic infections, rapidly emerges with suboptimal therapy (potentially through non-compliance) and this has tempered enthusiasm for the long-term efficacy of current antiretroviral combinations. Guidelines for prophylaxis of opportunistic infections are still based on lowest measured CD4<sup>+</sup> count, symptoms and prior opportunistic infections [58]. However, recent evidence suggests that primary prophylaxis against PCP may be discontinued when there is virological and immunological response to HIV therapy. HIV RNA viral load tests are useful in guiding the initiation and monitoring of therapy, but their usefulness in guiding prophylaxis has not yet been fully evaluated.

Prophylaxis against PCP with co-trimoxazole (described later) is also effective prophylactic therapy for toxoplasmosis and gives some protection against bacterial pathogens. Primary prophylaxis against *M. avium-intracellulare* infection is usually initiated when the CD4<sup>+</sup> count is less than  $0.1 \times 10^9/L$ . Clarithromycin or azithromycin (in combination with rifabutin) not only protects against *M. avium-intracellulare* but also reduces the incidence of, and hospital admissions due to, other bacterial infections [59,60]. Currently, prophylaxis against community-acquired respiratory tract infection is not recommended except in unusual circumstances such as recurrent serious bacterial infections. However, pneumococcal vaccine is recommended, preferably when the CD4<sup>+</sup> count is greater than  $0.2 \times 10^9/L$  [58], and probably should be repeated at 5-yearly intervals. In the USA it is also recommended that patients are immunized against influenza annually [58], although there is little evidence to justify this.

Prophylaxis against tuberculosis with isoniazid (300 mg daily) in African HIV-infected patients has been shown to be efficacious in purified protein derivative (PPD)-positive patients [61] and probably is also indicated in high-risk PPD-negative patients as this may reflect anergy due to immunosuppression. In the USA, where bacille Calmette-Guérin (BCG) is not available, a positive PPD skin reaction or contact with a case of active tuberculosis is an indication for prophylaxis, assuming there is no evidence of active disease [58]. Primary prophylaxis against endemic mycoses depends on place of residence and relative risk. There is evidence in appropriate settings for the efficacy of fluconazole against cryptococcosis [62]. The risks of primary prophylaxis include the emergence of drug-resistant organisms (particularly *Candida* spp.).

### ***Pneumocystis carinii* pneumonia**

On the basis of various microbiological characteristics, *P. carinii* is classed as a eukaryote as are protozoa, algae and fungi. It used to be regarded as a protozoon on the basis of

its morphology, and this supposition was supported by the responsiveness of the pneumonia that it causes to antiprotozoal antibiotics. However, ultrastructural findings, DNA sequencing and other molecular data have now led taxonomists to classify it as an atypical fungus [63,64]. Such considerations have been of no practical consequence to clinicians who are well aware that, unlike fungi, *P. carinii* cannot be cultured on cell-free media nor is it susceptible to treatment with any antifungal agents that target the usual fungal pathway of sterol synthesis (see Chapter 9).

*P. carinii* exists extracellularly in the form of tiny unicellular trophozoites. These form cysts, each cyst containing up to eight sporozoites or 'intracystic bodies'. Once mature, the cyst ruptures and the released sporozoites complete the life cycle as new trophozoites.

*P. carinii* is not a recent discovery. The organism was first described over 80 years ago in guinea-pig and rat lung and was mistakenly thought to be trypanosomal by Carini, after whom it was later named [65]. Infection of the lungs of mammals by strains of *P. carinii* appears to be species specific, with no good evidence of transmission from animal to humans and no known animal reservoirs. It is of low pathogenicity and was first associated with pneumonia in malnourished and debilitated institutionalized children on the European mainland during the Second World War, subsequently being identified as a cause of pneumonia in premature infants in the 1950s [65,66]. By the 1970s *P. carinii* had become a fairly well-recognized but somewhat infrequently diagnosed opportunistic cause of pneumonia in immunocompromised patients, particularly those receiving chemotherapy for leukaemia and other forms of cancer [67]. Reports of outbreaks of PCP in 1981 in previously healthy homosexual men and intravenous drug abusers led to the recognition and description of AIDS [25,26]. The incidence of PCP increased dramatically in the early 1980s in parallel with the AIDS pandemic.

## Epidemiology

Although *P. carinii* only causes disease in susceptible individuals who are significantly immunocompromised, harmless infection by this organism appears to be common and antibodies to *P. carinii* have been found to develop in the majority of non-immunosuppressed persons before the age of 13 years [68,69]. This has led to the suggestion that PCP is caused by a reactivation of latent infection that occurs once the patient's resistance has become sufficiently impaired. Opposing this hypothesis have been the negative findings of absent *P. carinii* DNA when lung tissue from immunocompetent patients has been examined using sensitive DNA amplification polymerase chain reaction (PCR) techniques [70]. Although no environmental reservoir of human pathogenic *P. carinii* has been identified, the organism has never-

theless been detected in outdoor air samples [71]. Furthermore, cluster cases have been described in groups of immunodeficient patients, implying that case-to-case transmission may occur [72], and *P. carinii* DNA has also been detected in air filters serving the rooms of units in which patients with PCP have been managed, supporting the hypothesis of airborne transmission [73]. The chance of such transmission is evidently low, so that it is not general practice to isolate patients with PCP. It seems probable that (i) the population in general encounters environmental *P. carinii* [71] and develops immunity against it [68,69], (ii) patients whose cell-mediated immunity becomes sufficiently impaired are susceptible to reinfection and colonization with the subsequent development of PCP [74,75] and (iii) airborne spread of the organism may occur between susceptible individuals who come into close contact with one another [72]. The reported incidence of PCP in sub-Saharan Africa in patients with HIV infection has been much lower than found in Europe and North America, probably as a result of earlier deaths from bacterial infection including tuberculosis, which is much more prevalent in the countries of these regions [76].

## Susceptibility

PCP occurs almost exclusively in the immunocompromised host. The chief characteristic of conditions that predispose to PCP is impaired cell-mediated immunity, as may be found in patients with HIV infection, those receiving chemotherapy for haematological and solid malignant lesions, those receiving immunosuppressive drugs following organ transplantation or for other inflammatory conditions, and premature infants and those suffering from protein malnutrition and primary immunodeficiency disorders. Highly unusual cases have been reported in elderly adults without apparent predisposing causes [77], although it is possible to speculate that these patients may have had subtle immune defects that went undetected. Although cell-mediated immunity is the primary defence against *P. carinii*, it is possible that defects of humoral immunity may play a role since PCP has exceptionally occurred in patients in whom only B-cell defects have been detectable [78].

HIV-seropositive patients are at greatest risk of PCP, although this risk has been substantially reduced by chemoprophylaxis. Without chemoprophylaxis, PCP was the AIDS-defining diagnosis in about 47% of HIV-seropositive patients in Europe and North America, this figure having fallen progressively to about 15% following the gradual uptake of chemoprophylaxis [79–82]. Despite this reduced incidence, PCP remains the most common opportunistic lung infection in HIV-infected patients in the western world; in one North American cohort, 28% of patients developed PCP at some point in their illness

despite chemoprophylaxis, this intervention delaying the onset of the first AIDS-defining illness by 6–12 months, by which time the CD4<sup>+</sup> count was lower [79]. The risk of developing PCP in HIV-infected patients correlates with the number of circulating CD4<sup>+</sup> lymphocytes, patients with counts of less than  $0.2 \times 10^9/L$  being at considerably greater risk than those with counts above this level [83,84]. It is also recognized that there may be a transient but quite profound fall in the CD4<sup>+</sup> count in patients at the initial or 'primary' stage of their infection, at which time they are in the process of seroconversion, and that this early fall may also result in PCP [85].

Patients receiving chemotherapy for malignant disease are at risk, particularly those with haematological neoplasms that may themselves impair cellular immunity. Acute lymphocytic leukaemia was the prominent disorder reported as predisposing to PCP before 1970 [67], although the disease also arises during the course of chemotherapy for lymphomas as well as other neoplastic diseases. The infection is unlikely to occur until 1 month of chemotherapy has elapsed. Treatment with fludarabine is thought to carry a particular risk of PCP [86].

PCP following organ transplantation is most likely from the onset of the second to the sixth month following the procedure, during which time immunosuppression is usually at its highest, although the infection may occur beyond these boundaries if immunosuppression is also required preoperatively or if it has been intensified at a later stage because of rejection [2]. In most centres, the incidence of PCP in those transplant patients who do not take prophylaxis is reportedly 10–12%, whereas in those who do the risk is largely eliminated [2].

Of the group receiving immunosuppressive therapy for other conditions, patients with Wegener's granulomatosis appear to be at particular risk of PCP, an incidence of 6% having been reported in one large retrospective group who did not receive prophylaxis [87]. All these patients were receiving a corticosteroid as well as another immunosuppressive agent. Further groups at risk include those receiving potent immunosuppressive treatment for other antineutrophil cytoplasmic antibody-positive vasculitis, connective tissue disorders such as systemic lupus erythematosus, polymyositis/dermatomyositis, rheumatoid arthritis and severe skin diseases [88].

A review from a single large North American centre of 116 cases of PCP occurring in patients who were not infected with HIV found that the first episode of PCP was associated with haematological malignancy in 30% of cases, organ transplantation in 25%, inflammatory disorders in 22%, solid tumours in 13% and other miscellaneous conditions in 10%. Over 90% of patients had been treated with systemic steroids, the median daily dose being up to 30 mg, although one-quarter of patients had received about half this dose [89]. The incidence of PCP in such susceptible groups may be reduced by the use of

chemoprophylaxis and also by control of the retroviral load in patients with HIV infection.

### Pathophysiology

*P. carinii* is an obligate extracellular pathogen. The trophozoite is believed to become attached to alveolar epithelial cells (principally type I pneumocytes) by mechanisms that include the formation of fibronectin bridges, following which the cell membrane of the invading organism interdigitates with the surface epithelium of the host cell to form a more intimate attachment, a process which may take 2 days. In the immunocompetent host, the invading organisms are phagocytosed by alveolar macrophages, although there are also humoral responses with the production of IgG and IgM antibodies against various *P. carinii* antigens. Experimental studies using immunosuppressed rodents imply that, given favourable circumstances, the organism enters a slow proliferative reproductive phase, so that it may take several weeks before large numbers of organisms have been produced. These developments result in cellular damage to the alveoli, with destruction of type I and subsequent proliferation of type II pneumocytes. Disruption of the epithelial barrier causes increased alveolar–capillary membrane permeability so that the alveolar spaces tend to fill with a foamy, vacuolated, proteinaceous, eosinophilic exudate (Fig. 52.11) containing cellular debris, surfactant and the cysts of *P. carinii*, which are up to 7 µm in diameter.

As with yeasts, the cyst walls of *P. carinii* contain β-1,3-glucan that allows them to take up fungal stains such as Grocott–Gomori methenamine silver nitrate, which marks the cyst walls black and is the most valuable histological *P. carinii* 'search stain' (Fig. 52.12). The alveolar exudate also contains numerous trophozoites. Although these do not take up the foregoing stain and are less easily seen with light microscopy, they may be shown as minute dots in the alveolar spaces with polychromatic stains such as Giemsa or the rapid modified Wright–Giemsa (Diff Quik), as may the intracystic sporozoites. Immunofluorescent staining with conjugated anti-*P. carinii* monoclonal antibodies also demonstrates brightly stained cysts and is a very useful microbiological search technique (see p. 1368).

The foregoing alveolar changes are associated with a patchy inflammatory interstitial infiltrate, which may become more chronic with interstitial and intraluminal fibrosis. Increased phospholipase activity may result in the degradation of surfactant with subsequent microatelectases, which are likely to contribute to physiological shunting, reduced lung compliance and hypoxaemia [70,78]. Atypical histological findings in PCP may occur and include modular forms with granuloma formation, cavitation, local consolidation, hilar lymphadenopathy, interstitial microcalcification and vascular infiltration [64,90]. Small pleural effusions are sometimes found. The

**Fig. 52.11** Section of lung from AIDS patient showing alveoli containing granular material of *Pneumocystis* pneumonia and some larger cells (one arrowed) with inclusions typical of cytomegalovirus (haematoxylin & eosin  $\times 460$ ). (Courtesy of Dr Nick Francis.)

pneumonic process more usually arises multifocally and is diffuse, although a predominantly upper lobe distribution may be encountered in patients who develop PCP despite prophylaxis with nebulized pentamidine [91–94], an observation explained by the relative alveolar hypoventilation that occurs in the uppermost parts of the lungs in the upright posture in humans [95]. Unusually, *P. carinii* infection may become disseminated in an extrapulmonary fashion to lymph nodes, bone marrow, spleen, liver, etc., so that virtually any organ system may become involved [96].

### Clinical features

Most patients have a low-grade fever, a dry cough and dyspnoea that progresses from mild breathlessness on physical exertion to tachypnoea at rest [64,97]. Less than one-third of patients produce sputum without induction (see below) and less than one-quarter experience chest pain [97]. The duration of symptoms from onset to diagnosis is highly variable, as some cases may be fulminant whereas others may be quite insidious. In general, PCP complicating HIV infection is more insidious, with a

median time from onset of mild symptoms to diagnosis of 4 weeks, whereas the same condition complicating other disease states tends to be more acute in its onset and development [98]. Patients with initially mild and insidious symptoms may postpone a visit to the physician until later in their illness but nevertheless present in a sick and uncomfortable state. On physical examination the patient may be febrile and tachypnoeic. Added sounds such as scattered crackles or, less commonly, wheezes may be heard but are absent in over half of cases. Patients may present with spontaneous pneumothorax and this occurrence in HIV-positive patients is highly suggestive of underlying PCP with subpleural cyst formation. Patients with HIV infection usually have noticed moderate to severe weight loss and oropharyngeal thrush may be present with other stigmata of HIV infection. In patients with typical clinical features of PCP but in whom HIV status is not known, a careful assessment of risk factors for HIV infection should be made. However, a lack of risk factors does not exclude a diagnosis of PCP and therefore the possibility of this treatable condition should not be neglected in 'low-risk patients'.

### Investigation and diagnosis

Whether it is desirable to investigate all patients with suspected PCP to a definite microbiological conclusion is somewhat controversial. On the one hand, there is the desire to be sure of the diagnosis before submitting the patient to a potentially toxic antimicrobial regimen, on the other the wish to initiate treatment as speedily as possible while sparing the patient uncomfortable and potentially

hazardous tests. Very often some sort of compromise has to be reached depending on the individual circumstances of the case and the facilities available in the institution. Sometimes the diagnosis of PCP seems so probable that treatment may be started without confirmation. Such a situation is illustrated by the patient known to be HIV-positive and who presents with a typical history of exertional dyspnoea, a non-productive cough, arterial hypoxaemia and whose chest radiograph shows diffuse bilateral hazy interstitial infiltrates, with no features to suggest bacterial pneumonia [99]. There is evidence that such an empirical approach is not associated with any worse outcome [100], although it should be realized that the diagnostic yield from BAL, should this subsequently become necessary, may decline within a few days of treatment [101].

### Diagnostic imaging

Patients with early PCP may sometimes develop mild symptoms before the appearance of any definite chest radiographic abnormality. This is more frequently found in HIV-positive than HIV-negative patients so that a normal chest film does not rule out the diagnosis of PCP [93]. The most typical early abnormality in PCP is that of bilateral, hazy, ground-glass, perihilar infiltrates with sparing of the lung peripheries (Figs 52.13 & 52.14). As the disease progresses, more homogeneous consolidation with air bronchograms may develop. These typical appearances may occur in up to 80% of all cases [93]. Ultimately the lungs may become massively consolidated and seemingly airless (Figs 52.15 & 52.16). The radiographic

**Fig. 52.15** More extensive bilateral infiltrates in *Pneumocystis* pneumonia with apparent peripheral sparing. (Courtesy of Dr Diana Buchanan.)

**Fig. 52.16** Extensive infiltration in severe *Pneumocystis* pneumonia. (Courtesy of Dr Diana Buchanan.)

changes in PCP have been reviewed and less common appearances include (i) more focal infiltrates; (ii) nodular appearances, sometimes with cavitation (coarse multiple nodules in the HIV patient usually indicate disseminated Kaposi's sarcoma and sometimes fungal disease); (iii) selective upper lobe involvement that may mimic mycobacterial disease, this sometimes occurring in patients who have developed PCP despite nebulized pentamidine prophylaxis; (iv) subpleural cyst formation (also associated with pentamidine prophylaxis) and sometimes leading to secondary spontaneous pneumothorax; (v) hilar lymphadenopathy; and (vi) small pleural effusions and changes consistent with bronchiectasis [90,93,94]. With successful treatment there is gradual clearing of the diffuse infiltrates over a period of weeks or even months as the patient improves, radiographic resolution commonly lagging behind clinical improvement.

High-resolution CT may be useful in excluding *Pneumocystis* pneumonia when the history is suspicious but the chest radiograph remains normal, in which case an incidence of PCP of 12% has been reported [102]. Such scans may show bilateral ground-glass opacification, sometimes with sparing of the subpleural lung tissue. Less commonly, there may be some lobular inhomogeneity that can result in a mosaic pattern in which ground-glass involvement is interspersed with normal lung appearances. However, CT need not be carried out as a matter of routine in more typical cases as the images may not add clinically

useful information to that obtained from plain radiographs. Subpleural cysts may sometimes be clearly shown. Nuclear medicine scans using gallium-67 or indium-111 have also been used in the investigation of PCP in some centres, although the uptake of these investigations, which lack specificity and are both expensive and cumbersome, has not been widespread [64,103].

#### Non-microbiological investigations

The CD4<sup>+</sup> count is a very useful predictor of the likelihood of PCP in patients with HIV infection; it has been found that PCP is unlikely to develop in HIV-infected patients with CD4<sup>+</sup> counts above  $0.2 \times 10^9/L$ , whereas patients with counts below this level have a greatly enhanced risk [84]. A number of other tests have been found to have a helpful negative predictive value despite a low specificity, so that a normal result makes PCP unlikely but an abnormal result could be due to a number of different conditions and does not rule it out.

Serum lactate dehydrogenase levels are usually raised in PCP [104], although it has been suggested that this non-specific finding may simply correlate with the degree of radiographic abnormality irrespective of the pathogen [105].

Similarly, the finding of a normal diffusing capacity (DLCO) for carbon monoxide in a patient at risk of PCP who has mild symptoms and a chest radiograph that looks

normal makes this diagnosis highly improbable, whereas the finding of a reduced *DLCO* or one that shows a downward trend in such a patient is suspicious enough to lead to further investigation for PCP [106].

An exercise test with simple monitoring of oxygen saturation by pulse oximetry may also be useful for excluding PCP in doubtful cases, since treadmill testing in 85 HIV-positive patients suspected of having PCP found that a 3% fall in saturation with exercise was 100% sensitive with a specificity of 70% [107]. Once again this test may be used to screen outpatients with normal or minimally abnormal chest radiographs and normal resting saturations, in which case a failure to desaturate with exercise effectively rules out PCP [64].

Arterial blood gas analysis is an essential assessment of severity, as with any pneumonia, although in the early stages of PCP is likely to be normal. Patients with PCP are commonly anaemic as a result of their underlying disease or its treatment. The total white cell count is more often normal or low rather than raised. Hypoalbuminaemia is not uncommon.

## Microbiological investigations

### *Induced sputum analysis*

Most patients with PCP do not produce sputum. In those few that do, a good specimen should be submitted to the microbiology department and the physician should make sure that the laboratory staff are aware of the nature of the clinical problem in order that the material be dealt with quickly and to best effect.

Sputum production may be induced in the majority of patients whose coughs are dry [7]. The specimen is obtained by having the patient breathe a mist of nebulized saline, which causes coughing. A hypertonic (2.7–5%) saline solution is conventionally used, a jet nebulizer being driven at a flow rate of at least 6 L/min and being applied to the face with a mask. Ultrasonic nebulization may be used as an alternative. The mouth should first be prepared by teeth cleaning, mouth rinsing and gargling in order to reduce any proteinaceous debris to a minimum, as this might otherwise obscure the organism. The procedure is at best unenjoyable and some patients find it distinctly unpleasant, so that it needs to be supervised by motivated staff, ideally an experienced physiotherapist, in order that an adequate specimen is obtained [108]. Sensible precautions should be taken to protect other patients from the dissemination of microorganisms during this process. Since the differential diagnosis often includes infection with *M. tuberculosis*, it is advisable to perform the investigation in a negative air flow room with attention paid to the safety of staff and visitors. A small percentage of patients may develop nausea, vomiting or wheeze and some may develop arterial desaturation [109]. It is never-

theless usually possible to obtain a satisfactory sample, although sputum induction is poorly tolerated by the more breathless subject and may prove impossible in up to 20% of patients. Although the test has been claimed to be very sensitive (up to 92%) by some groups [110], its usefulness is highly dependent on procedures being meticulously followed from the bedside to the laboratory. A sensitivity for PCP in HIV-positive patients of 28% was found on adequate samples by an experienced group in 1991, compared with 73% for BAL (see Chapter 8) [108]. Many centres now report higher sensitivities for both tests [110] so that the more invasive BAL may be avoided in a significant number of patients. A high sensitivity (63%) for induced sputum analysis has also been reported in patients with PCP due to disease other than HIV infection [111], although it might be expected that the yield in this group would be lower, as the alveolar burden of *P. carinii* is not usually as high in the absence of HIV infection [112].

Many laboratories now examine sputum for *P. carinii* using a direct immunofluorescent test (DIFT), which employs anti-*P. carinii* monoclonal antibodies and which demonstrates brightly stained cysts and results in significantly improved sensitivity compared with standard staining methods [113]. However, a negative induced sputum analysis by no means excludes PCP and it is usual for BAL to be carried out in such patients.

### *More invasive sampling techniques*

Bronchoscopic sampling is appropriate for cases of suspected PCP in whom induced sputum analysis has been negative or as the initial investigation in centres where the positive yield from induced sputum is too low to make the test worth while. One retrospective review of all cases of suspected PCP in a large North American centre over a 4-year period found that a positive diagnosis was made bronchoscopically in 50% of patients in whom induced sputum had been negative, PCP being confirmed in over half of these, other common diagnoses including tracheobronchial Kaposi's sarcoma (diagnosed by its visual appearance), tuberculosis and cryptococcal pneumonia [114]. There have been reports of diagnostic sensitivities of over 90% for PCP using both BAL and transbronchial lung biopsy, although these high success rates have generally been achieved in populations with a high prevalence of HIV-positivity. Some centres add transbronchial lung biopsy to BAL as a matter of routine, in the belief that it increases the likelihood of reaching a positive diagnosis, particularly as a significant number of patients may turn out to have diagnoses other than PCP; thus a retrospective European study involving 142 immunocompromised patients found that the *overall* diagnostic yield was 68% for transbronchial lung biopsy compared with 36% for BAL [115]. However, the same authors found that when the diagnosis was found to be PCP, there was little difference

in yield between transbronchial lung biopsy and BAL [115]. Many centres therefore use BAL without biopsy as the initial invasive diagnostic procedure of choice when the chance of PCP seems high, and use transbronchial biopsies only in selected cases. Thus a retrospective study covering a 3-year period in a large North American centre investigated the bronchoscopic results in patients with suspected PCP. Paired samples of both BAL fluid (examined using monoclonal antibody DIFT) and transbronchial lung biopsies (examined using conventional silver staining) showed that the one-fifth of patients in whom samples were adequate had PCP and that the sensitivity for DIFT on BAL fluid was 95% compared with 43% for silver staining on biopsies [116]. These and other seemingly conflicting results reported in the literature may result from methodological variables as well as from differences in the patient populations studied, so that individual clinicians may wish to modify their own approach according to the results of local audit. A decision to obtain histology for transbronchial biopsy may become necessary if less invasive methods have not produced a definitive diagnosis or if the patient is failing to respond to empirical antimicrobial therapy. It carries an increased risk of pneumothorax and haemorrhage. Brush biopsy does not increase the yield. It may occasionally be necessary to obtain a larger block of tissue by thorascopic or open lung biopsy (see Chapter 8).

Although the diagnostic yield may be increased by the use of PCR to detect *P. carinii* DNA in specimens such as induced sputum or BAL fluid [117,118], this costly investigation, which is not routinely available, may mislead as positive results may be obtained in the presence of residual non-viable organisms that may persist for some weeks after successful treatment of PCP.

### Supportive treatment

Patients who die as a result of PCP do so because of worsening tissue hypoxia, so that immediate steps should be taken to assess the level of hypoxaemia and to correct it appropriately. This basic respiratory support is provided by high-flow oxygen administered using standard face masks. If  $P_{aO_2}$  cannot be adequately maintained using high-flow oxygen via a mask with a reservoir bag, then the addition of continuous positive airway pressure by mask should be considered, provided that a pneumothorax has been excluded [119]. This may be well tolerated since sputum production is often minimal and it presumably improves oxygenation by splinting open small airways. Nasal positive-pressure ventilation may also improve gas exchange and avoid intubation. Patients who continue to deteriorate despite these measures remain tachypnoeic and become increasingly exhausted with worsening hypoxaemia ( $P_{aO_2} < 6.7$  kPa, 50 mmHg) and eventually become hypercarbic. An individual decision has to be

made in this situation about whether to intubate and mechanically ventilate the patient [120]. Ideally, this should be based on a knowledge of the patient's underlying disease and its prognosis, the patient's quality of life and any wishes that he or she might have expressed. Suffice to say that although the mortality is high in patients with PCP who require ventilation, particularly those with HIV infection [121], the authors have nevertheless seen successful outcomes, particularly in patients whose predisposing disease was controlled and whose performance was not significantly reduced before the onset of the pneumonic symptoms.

### Antimicrobial treatment

Pentamidine isethionate (see Chapter 9) is an antiparasitic agent that has been used for over 50 years in the treatment of African trypanosomiasis (sleeping sickness) and leishmaniasis (kala-azar). It was found to be effective against *P. carinii* in the 1950s, and PCP is the only respiratory application for this drug. The use of pentamidine increased both as a result of the AIDS pandemic and the increasing use of immunosuppressant therapy in medicine. In the 1970s, co-trimoxazole, a combination of trimethoprim and sulfamethoxazole (sulphamethoxazole) (see Chapter 9), emerged as an alternative drug for treating PCP, having been found to be as effective as pentamidine but with fewer side-effects when used in children [122]. Although there have been no large comparative trials of the two, there is evidence that both response time and survival are better with co-trimoxazole [123], which has subsequently been adopted as the treatment of choice for PCP both in HIV infection and other disease [124]. Adverse effects with co-trimoxazole remain a major problem in view of the high doses that have to be used. This is particularly so in those patients with AIDS, in whom side-effects are reported in 50–80% of cases leading to discontinuation of the drug in as many as 57% [97,125], whereas the adverse side-effect rate is lower (10–20%) in other immunosuppressed patients [97].

It is accepted practice to treat the iller, more hypoxic patient intravenously, the drug of choice being co-trimoxazole, with pentamidine as a second-line agent if co-trimoxazole cannot be tolerated. Intravenous/trexate trimetrexate/folinic acid (see Chapter 9) may be used as a third-line agent for patients who are intolerant of, or unresponsive to, co-trimoxazole and pentamidine [97].

The patient with mild disease ( $P_{aO_2} > 10$  kPa, 75 mmHg) may be treated with oral therapy, co-trimoxazole being the drug of choice. Orally administered alternatives for the intolerant patient are dapsone–trimethoprim, atovaquone or clindamycin–primaquine. The main drug regimens are illustrated in Table 52.8. Treatment of PCP in patients with HIV infection should be followed by lifelong prophylaxis.

Drugs	Dosage	Route
<i>First line</i>		
Co-trimoxazole	90–120 mg/kg daily in three to four divided doses	Oral or i.v.
<i>Second line</i>		
Pentamidine	3–4 mg/kg daily over 1–2 h once daily	i.v.
<i>Alternatives</i>		
Trimetrexate	45 mg/m <sup>2</sup> trimetrexate once daily 20 mg/m <sup>2</sup> calcium folinate four times daily	i.v. i.v. or oral
Dapsone–trimethoprim	100 mg dapsone once daily 15 mg/kg daily trimethoprim in two to four divided doses	Oral Oral
Atovaquone	750 mg two to three times daily	Oral
Clindamycin–primaquine	See text	i.v. and oral or oral

**Table 52.8** Antimicrobial treatment for *Pneumocystis carinii* pneumonia (see text for details).

### First-line treatment with co-trimoxazole

The conventional dose of co-trimoxazole required to treat PCP is 20 mg/kg daily of trimethoprim and 100 mg/kg daily of sulfamethoxazole, usually expressed as 120 mg/kg daily of the combined preparation. It is usual to administer co-trimoxazole as three to four divided doses and to treat for at least 2 weeks in the case of non-AIDS-associated PCP and for 3 weeks in the presence of HIV infection, provided that the therapy is tolerated and that a clinical response is taking place. In all but the milder case of PCP ( $\text{PaO}_2 > 10 \text{ kPa}$ , 75 mmHg), the course of co-trimoxazole is usually given intravenously for the first 10 days or so, using the same 120 mg/kg daily schedule. The manufacturer's recommendation is that the intravenous fixed combination preparation should be diluted 1/25 in 0.9% saline or 5% dextrose solution, i.e. 125 mL to one 480-mg co-trimoxazole ampoule (5 mL), and infused over 90–120 min. Despite this recommendation, it is probably safe to reduce the volume to 75 mL 5% dextrose per 480-mg ampoule if volume overload is likely to be a problem [126]. Patients with PCP receiving intravenous co-trimoxazole may deteriorate before they start to improve (see p. 1372) and a significant improvement in oxygenation may not be seen for 4–9 days. Patients with HIV-associated disease tend to respond more slowly than those without, so that it should not be assumed that therapy with co-trimoxazole has failed in such cases until about a week has passed [127]. Before switching treatment, it also has to be borne in mind that apparent deterioration may be caused by superadded pulmonary infection with bacteria or other pathogens, by coexisting disease such as Kaposi's sarcoma or lymphoma, or by complications such as pneumothorax or pulmonary oedema due to fluid overload. Once clear clinical improvement occurs, the course may be com-

pleted orally as the drug combination is well absorbed in the absence of gastrointestinal disease [125].

Milder cases may be treated orally from the start [64] provided that they have no problems with absorption, and this may be done under outpatient supervision. It is common practice to achieve this by prescribing 1920 mg (as two double-strength 960-mg tablets) three or four times daily. In patients who are finding it difficult to tolerate the drug, it may prove possible to reduce the total daily dose by 25%, from the usual 120 mg/kg daily to 90 mg/kg daily, without losing efficacy [128]. Dosage reductions are also made in renal insufficiency. The full dose may be given if the estimated creatinine clearance (see Chapter 9) is greater than 30 mL/min, the dose being halved in the range 15–30 mL/min and omitted completely if less than 15 mL/min. It is possible to assay drug levels of trimethoprim and sulfamethoxazole in such situations in order to attempt to maintain the trimethoprim level in the range 5–8 µg/mL and the sulfamethoxazole level in the range 100–150 µg/mL.

The necessity for 3-week courses has been questioned and it may be possible to conclude treatment after 2 weeks in the face of adverse effects if the patient has apparently responded and provided that secondary prophylaxis is started at the conclusion of the course [129]. It is advisable during treatment to check urea/creatinine and electrolytes, blood count and liver function tests at least twice weekly because of the likelihood of adverse effects.

Adverse effects (see Chapter 9) are common when high-dose co-trimoxazole is used in the above fashion to treat PCP, particularly when the patient has AIDS, in which case the drug may need to be discontinued in about 30% of cases [130]. Side-effects usually become evident after 1–2 weeks of treatment and include nausea and vomiting (25%), anaemia and neutropenia (40%), thrombocytopenia

(5%), abnormalities of liver function (10%), rashes (20%) and fever (25%) [123,124]. The drug need not be discontinued for mild rashes, which may be managed with antihistamines without progression [131]. Patients who have had co-trimoxazole rashes in the past have been successfully rechallenged on subsequent occasions, although severe systemic reactions may occur so caution should be exercised [131]. Rashes with involvement of the mucous membranes or those associated with the formation of bullae are reasons for discontinuance, as is intractable pruritis. The potential for marrow depression may be increased by other drugs such as zidovudine and ganciclovir, which should be stopped while treatment with high-dose co-trimoxazole is in progress. Trimethoprim has a mild potassium-sparing diuretic effect that may produce hyperkalaemia. Uraemia, hypocalcaemia and hyponatraemia sometimes occur. As with other antibiotics, *Clostridium difficile* colitis may occur. Patients with a previous history of a rash and fever in relation to co-trimoxazole have been given 8-day courses of desensitization, involving three or four times daily oral dosing with initially tiny concentrations of co-trimoxazole in solution prepared by diluting the standard oral suspension (240mg/5mL) [127]. One practical method is to start with a 1/10<sup>6</sup> dilution on day 1, giving 1, 2, 4 and 8 mL doses at 6-h intervals, then continuing with the same volumes at 6-h intervals but reducing the dilution by a tenth power each day until day 7 when a 1/1 dilution of 20mg sulfamethoxazole and 4mg trimethoprim is reached. On day 8 the standard oral suspension is given as 1, 2 and 4 mL for the first three doses, culminating in one double-strength tablet for the fourth dose. Such desensitization should not be attempted in patients who have previously experienced a serious skin reaction such as Stevens–Johnson syndrome or toxic epidermal necrolysis [132]. The overall rate of intolerance to co-trimoxazole is reduced in patients ill enough to require adjuvant corticosteroids (see below) [133].

### Second-line intravenous treatment with pentamidine

Intravenous pentamidine (see Chapter 9) may be used as an alternative treatment in patients who are intolerant or unresponsive to co-trimoxazole. It is probably as effective as co-trimoxazole but is more toxic [123]. It is given as a single daily dose of 3–4 mg/kg diluted in 250 mL of 5% dextrose solution (infused slowly over 1–2 h to prevent hypotension) and continued for 3 weeks in patients with AIDS; those with non-HIV-related PCP are sometimes treated for 2 weeks. Adverse effects from pentamidine are sometimes avoided by switching therapy after about 10 days to a less toxic oral regimen, such as trimethoprim in combination with dapsone or atovaquone singly, in order to complete 3 weeks of treatment. Nebulized pentamidine in doses of up to 8 mg/kg daily has been used to treat less

severe PCP but patients respond more slowly, the mortality rate is significantly higher and relapse is more common; thus this route of administration is rarely used other than for prophylaxis [127,134].

As with co-trimoxazole, adverse effects are frequent and include renal impairment (60%), leucopenia (45%), nausea and vomiting (25%), hypotension (25%) and hypoglycaemia/hypocalcaemia (20%) [123]. Fewer side-effects are encountered if 3 mg/kg daily is used. Hypotension is avoided by the slow infusion rate and blood pressure should be monitored as should serum urea/creatinine, electrolytes, glucose and calcium. Other side-effects are described in Chapter 9.

### Alternative intravenous treatment with trimetrexate–folinate

Trimetrexate (an analogue of methotrexate) may be used as third-line treatment in hospitalized patients who are intolerant of both co-trimoxazole and pentamidine or in whom these drugs have failed. However, some experts use trimetrexate–folinate alone or in combination with dapsone as a second-line treatment, in preference to the more toxic pentamidine, in patients intolerant of co-trimoxazole or in whom this drug has failed [125]. Trimetrexate has its effect by preventing *P. carinii* from synthesizing folate. The folinate component of the regimen prevents or reduces myelosuppression, the microbe itself being unable to take up this supplement as it lacks a folate transport system.

The dose of trimetrexate is 45 mg/m<sup>2</sup> once daily intravenously for 21 days and that of calcium folinate (leucovorin) 20 mg/m<sup>2</sup> daily intravenously (at a separate site) or orally as four divided doses for 24 days [135]. Neutropenia is the main adverse effect, this being attenuated by folinate. Other possible adverse effects include oral and gastrointestinal mucosal ulceration, hepatic and renal dysfunction and peripheral neuropathy. However, the combination may be better tolerated than co-trimoxazole [136]. In one trial, trimetrexate–folinate proved less effective than co-trimoxazole, with a 69% survival compared with an 84% survival for co-trimoxazole at 7 weeks [135]. It is possible that the efficacy of trimetrexate–folinate may be improved by the addition of oral dapsone and this approach is being investigated.

### Alternative oral treatment using dapsone–trimethoprim

This orally administered combination may be used in patients with mild to moderate PCP ( $P_{aO_2} > 9.3$  kPa, 70 mmHg) who are intolerant of co-trimoxazole or in those cases with more severe intolerance to co-trimoxazole once the condition has been brought under control with pentamidine. The regimen is dapsone 100 mg daily as one dose, trimethoprim 15 mg/kg daily in two to four divided

doses for 21 days [127,137]. The response rate appears to be similar to that achieved with co-trimoxazole with fewer side-effects.

Adverse effects include rashes, nausea and vomiting, haemolytic anaemia, methaemoglobinaemia, neutropenia, thrombocytopenia and disturbances of liver function, hyponatraemia and mild hyperkalaemia. Dapsone results in the production of hydrogen peroxide that may reduce haemoglobin to methaemoglobin, a useless molecule that cannot carry oxygen and which may result in cyanosis. This process is accelerated in subjects who have glucose 6-phosphate dehydrogenase (G6PD) deficiency, so that dapsone should not be used in patients with this condition; patients who are not G6PD deficient are unlikely to become symptomatic from any associated methaemoglobinaemia. There are reliable screening tests that demonstrate decreased red cell G6PD activity in the blood of such patients. Although used in co-trimoxazole-intolerant patients, dapsone-trimethoprim should not be tried in those who have developed a serious skin rash or type I hypersensitivity reaction to co-trimoxazole.

#### Alternative treatment using clindamycin-primaquine

This combination (unlicensed for PCP in the UK) is an alternative in patients with mild to moderate PCP ( $P_{aO_2} > 9.3 \text{ kPa}$ , 70 mmHg) who are intolerant of co-trimoxazole and dapsone-trimethoprim; clindamycin is administered first intravenously and then orally and primaquine orally. It is also being increasingly used in the sicker patient as an alternative to intravenous pentamidine. Clindamycin may be given at a dose of 600 mg (450 mg if body weight  $< 60 \text{ kg}$ ) intravenously every 6 h for 10 days, then 450 mg orally four times daily for 11 days, primaquine being given at a single dose of 15 mg (30 mg base) for the whole 21-day course. A trial comparing this regimen with co-trimoxazole in patients with HIV-associated PCP of this severity showed similar rates for response, adverse effects and survival following completion of treatment for both groups [138]. Clindamycin-primaquine is probably of similar efficacy to dapsone-trimethoprim [139].

Adverse effects with clindamycin-primaquine are generally mild. They include nausea, vomiting, abdominal discomfort, diarrhoea (including *C. difficile* diarrhoea), disturbances of liver function, methaemoglobinaemia (primaquine especially in G6PD-deficient subjects, who may develop haemolytic anaemia and who should be screened out) [125] and fever. Rashes may occur in about 20% of recipients and neutropenia or other haematological toxicity in about 25% of patients with AIDS treated for PCP [124,130].

#### Alternative oral treatment using atovaquone

This orally administered compound is probably best

reserved for patients with mild PCP ( $P_{aO_2} > 10 \text{ kPa}$ , 75 mmHg) who are intolerant of co-trimoxazole and second-line oral regimens such as dapsone-trimethoprim or clindamycin-primaquine. It has good activity against *P. carinii* but its efficacy in clinical practice is impaired by relatively poor absorption, although this may be improved if the drug is taken with fatty food. It has a higher failure rate than co-trimoxazole [140]. It is best avoided in patients with malabsorptive problems, including those with diarrhoea [140]. The dose is 750 mg in tablet form taken with food three times daily, or 750 mg twice daily as a suspension, for 3 weeks. Side-effects are infrequent, possibly reflecting its poor absorption, although rashes (often transient), nausea, vomiting, disturbances of liver function and diarrhoea may occur, the latter further impairing absorption.

#### Adjunctive corticosteroids

It was found by serendipity that a patient with PCP recovered after receiving oral corticosteroids [141]. There followed a small trial that showed improvement when patients with respiratory failure received methylprednisolone as an adjunct to conventional therapy for PCP [142]. After this, a double-blind placebo-controlled trial was carried out that also used early adjunctive high-dose methylprednisolone in a similar group of ill, hypoxic and tachypnoeic patients with PCP. It had to be discontinued when it became statistically obvious that the group receiving placebo and co-trimoxazole were more likely to develop worsening respiratory failure and less likely to survive than the group receiving steroids. Similar improvements were then found in a further double-blind placebo-controlled trial when high-dose prednisolone rather than methylprednisolone was used, except that in this study patients who deteriorated initially on placebo improved when switched to steroids [143]. The accumulation of this and other evidence showed that early high-dose corticosteroids given as an adjunct to conventional antimicrobial treatment in patients with moderate to severe PCP can be expected to significantly reduce the chances of deterioration and death [127]. Patients with mild disease at presentation ( $P_{aO_2} > 10 \text{ kPa}$ , 75 mmHg) probably do *not* benefit from this intervention [144].

The mechanism by which corticosteroids produce these benefits is unknown but it has been suggested that they blunt the early inflammatory response associated with drug-induced death of *P. carinii* that might otherwise lead to deterioration before improvement sets in. A consensus view is that steroids should be used in patients with a  $P_{aO_2}$  of less than 9.3 kPa (70 mmHg) at the onset of treatment and that this intervention is probably of no value if delayed for more than 72 h. An appropriate regimen is prednisolone 40 mg twice daily for 5 days, 20 mg twice daily for 5 days, followed by 20 mg daily until completion

of the course of antimicrobial. Methylprednisolone may be used at 75% of the dose of prednisolone in patients who cannot take oral medication [127]. Whether or not a similar approach is applicable to patients who have PCP in the absence of AIDS is unknown, as most of the published work refers to HIV-positive patients. There is evidence to suggest that the early use of steroids has reduced the incidence of acute respiratory failure and the need for mechanical ventilation in patients with PCP, whereas those who progressed to respiratory failure requiring mechanical ventilation despite receiving steroids seem to fare worse as a group than those who had ventilation for PCP in the years prior to the introduction and general use of steroids in this situation [145].

One concern about adjuvant corticosteroids is that they could make matters worse if used inappropriately, for example in the presence of mycobacterial or CMV infection in the severely immunosuppressed patient [146].

### Prophylaxis

Patients belonging to the 'at-risk' categories described above should receive PCP prophylaxis. This may take the form of primary prophylaxis, intended to prevent the initial attack of pneumonia in a predisposed individual, or secondary prophylaxis, intended to prevent relapse after the successful treatment of a first episode. In the case of HIV infection this should be for life, since prior to the introduction of prophylaxis 60% of patients would experience a relapse within a year [147] and the median survival after the first attack of PCP was only 11 months [148]. There are now convincing data to indicate that PCP prophylaxis has had a significantly beneficial effect on the morbidity, mortality and healthcare costs of HIV [149–151]. It is currently recommended that prophylaxis in HIV infection should be given to patients in whom:

- 1 the CD4<sup>+</sup> count falls below  $0.2 \times 10^9/L$ ;
- 2 the CD4<sup>+</sup>/total lymphocyte ratio is less than 1:5;
- 3 there is oropharyngeal thrush or an unexplained fever for two or more weeks even if the cell counts exceed the values given above;
- 4 there is another AIDS-defining diagnosis, such as Kaposi's sarcoma, cerebral toxoplasmosis or cryptococcal meningitis;
- 5 there has been recovery from a previous episode of PCP [64,152].

The prophylactic agent of choice is oral co-trimoxazole. Alternative regimens use dapsone or nebulized pentamidine (Table 52.9). In practice it is common for a patient with HIV infection to start with one drug regimen and to switch to another because of poor tolerance or interaction with other drugs.

Pregnancy is not a contraindication to PCP prophylaxis. Co-trimoxazole remains the drug of choice and may be used in pregnancy, although some physicians prefer to

**Table 52.9** Antimicrobial prophylaxis for *Pneumocystis carinii* pneumonia.

Drugs	Doses
Co-trimoxazole	960 mg once daily* <i>or</i> 480 mg once daily* <i>or</i> 960 mg three times a week
Dapsone	100 mg once daily <i>or</i> 50 mg twice daily
Dapsone–pyrimethamine	Dapsone 50 mg once daily Pyrimethamine 50 mg once a week Calcium folinate 25 mg once a week <i>or</i> Dapsone 200 mg once a week Pyrimethamine 75 mg once a week Calcium folinate 25 mg once a week
Pentamidine (nebulized)	300 mg once monthly (appropriate nebulizer, see text)

\* Regimens of first choice.

Routes of administration oral except for pentamidine.

withhold systemic treatment in the first trimester because of theoretical concerns about teratogenicity, in which case they may opt for nebulized pentamidine in these first 12 weeks because little of it is systemically absorbed.

### Co-trimoxazole

Co-trimoxazole is the most effective form of primary prophylaxis for PCP in HIV infection and is taken as one double-strength tablet (960 mg) once daily, this being the regimen of first choice [152]. This results in a low attack rate of PCP of about 0.5% per year in patients with HIV infection [153]. Three-times weekly dosing with one double-strength tablet may bring the attack rate up to about 1.8% per year but produces almost a 50% reduction in toxicity and thus is an acceptable alternative regimen if higher doses cannot be tolerated [153]. However, there is the risk that intermittent dosing may produce difficulties with compliance and therefore loss of efficacy. There is also strong evidence for the efficacy and substantial clinical benefit of one single-strength tablet (480 mg) daily and this is the preferred regimen if daily double-strength tablets cannot be tolerated [152]. When side-effects have not been severe an alternative is to attempt desensitization (p. 1371), this having been successful in over 70% of patients with some regimens [132]. The efficacy of co-trimoxazole may be better maintained in the face of a falling CD4<sup>+</sup> count in HIV infection than is the case with other prophylactic drugs. Resistance of *P. carinii* to co-trimoxazole has so far not been a problem. It also provides protection against toxoplasmosis, as well as bacterial upper and lower respiratory tract infections [152,153]. Its main drawback is its propensity to produce adverse effects such as rash (20%), fever, nausea and vomiting,

neutropenia, anaemia or abnormalities of liver function, all leading to reduced compliance so that between one-fifth and half of patients may need to switch therapy [127]. It is nevertheless still reasonable to persist with or resume co-trimoxazole prophylaxis in a patient who has previously experienced mild intolerance to this compound, although not if a skin reaction has been associated with mucositis, the formation of bullae or exfoliation [70]. It has not yet been shown whether it is best to reintroduce co-trimoxazole that has been discontinued at the same dose, at a lower dose, at a gradually increasing dose or whether desensitization should be tried. Co-trimoxazole has been found to provide more effective primary and secondary prophylaxis than nebulized pentamidine [154,155], although it is possible that this difference may only become evident once the CD4<sup>+</sup> count has dropped below  $0.1 \times 10^9/\text{L}$  [156]. Trimethoprim alone is not an effective prophylactic agent. Co-trimoxazole is also regarded as the most effective prophylactic therapy against PCP in other immunosuppressed groups, for example in transplant recipients one single-strength 480-mg tablet is prescribed for up to 12 months after transplantation. This has reduced the incidence of PCP following transplant from 10–12% to virtually zero, while also reducing the risk of infection by other pathogens, including *Listeria monocytogenes*, *Nocardia asteroides* and *Toxoplasma gondii* [2]. This dose may also be prescribed in other categories of non-HIV-infected immunosuppressed patients.

### Dapsone

Dapsone 100 mg daily (as a single dose or as 50 mg twice daily) may also be used as prophylaxis in patients who are intolerant of co-trimoxazole (and who may fail desensitization to it). Some studies have found dapsone to be as effective as co-trimoxazole [156,157]; however, its efficacy appears to diminish as disease advances so that the attack rate of PCP is about 7% per year once the CD4<sup>+</sup> count has fallen to less than  $0.1 \times 10^9/\text{L}$  [127,156]. Dapsone 50 mg daily is sometimes combined with pyrimethamine 50 mg per week and with calcium folinate (leucovorin) 25 mg per week, this combination having been found to be of similar efficacy to nebulized pentamidine in primary PCP prophylaxis but with more adverse effects [152]. An alternative is dapsone 200 mg, pyrimethamine 75 mg and calcium folinate 25 mg, all once weekly. Combinations that contain both dapsone and pyrimethamine are also protective against cerebral toxoplasmosis but not against bacterial infections. The incidence of adverse effects is broadly similar to that encountered with co-trimoxazole [157]. Although some data suggest a low incidence of side-effects in patients switched to dapsone after intolerance to co-trimoxazole [158], other data have shown that a high proportion of dapsone-treated patients become intolerant to it [156]. Nausea, rashes, fever, pancreatitis, liver enzyme

disturbances, leucopenia, methaemoglobinaemia and haemolytic anaemia in patients with G6PD deficiency may occur. Twice-weekly dosing produces fewer side-effects but carries a higher failure rate, as does a reduction in the dose to 50 mg daily [153,156]. Dapsone has been found to provide more effective primary prophylaxis than nebulized pentamidine, although it is possible that this difference may only become evidence once the CD4<sup>+</sup> count has dropped below  $0.1 \times 10^9/\text{L}$  [156]. There are concerns about the possible teratogenicity of pyrimethamine, which should be avoided in pregnancy.

### Aerosolized pentamidine

Aerosolized pentamidine was the first form of PCP prophylaxis to be used in HIV-infected patients and was shown to be effective in a placebo-controlled trial [159]. It is conventionally used at a single dose of 300 mg monthly. The type of jet nebulizer and the flow rate used are important in achieving adequate lung deposition, as the optimal particle size for alveolar deposition is 1–2  $\mu\text{m}$ . The production of this size of particle diminishes deposition in the more proximal respiratory tract and therefore reduces adverse effects. The system with which there is the most experience is the Respirgard II jet nebulizer (Marquest). This should be driven by air or oxygen at a flow rate of 6–8 L/min [160,161]. The System 22 Mizer (Medic-Aid) was also validated for use with pentamidine but is no longer available. Although other systems may be effective, this has yet to be clearly shown in published work. The principal advantage of nebulized pentamidine as prophylaxis is the relatively low incidence of adverse effects compared with other options such as co-trimoxazole or dapsone [154,156]. The main disadvantage is reduced efficacy compared with standard doses of co-trimoxazole or dapsone, this becoming particularly evident in AIDS when the CD4<sup>+</sup> count falls below  $0.1 \times 10^9/\text{L}$  [154–156]. Other disadvantages include the inability of topical pentamidine to prevent bacterial infection, cerebral toxoplasmosis or extrapulmonary *Pneumocystis* that arises as a result of haematogenous dissemination [147,152,155]. The inhalation of a nebulized solution is less convenient than swallowing a tablet and is five to ten times more expensive. It is best administered in a small room or booth with extraction to the exterior of the building because of the potential risk of the dissemination of tuberculosis [161]. Nebulized pentamidine is usually well tolerated. Cough is common and wheeze may occur in about 10% of recipients [162], although these may be prevented or diminished by first giving a dose of  $\beta$  agonist such as 200  $\mu\text{g}$  salbutamol from a standard metered-dose inhaler or 2.5 mg from a nebulizer. The patient may complain of an unpleasant metallic taste or nausea, as indeed may also be the case with parenteral administration, although nebulized pentamidine is usually free from the systemic side-effects seen when the

parenteral route is used (see above and Chapter 9) as little of it is absorbed [147]. It remains an important form of prophylaxis for patients who are intolerant of co-trimoxazole and dapsone and who are at low risk of cerebral toxoplasmosis [155,163], although nowadays most patients manage one of the oral regimens satisfactorily.

## Complications

Patients who develop frank respiratory failure as a consequence of PCP commonly display the clinical features of ARDS, with a virtual radiographic 'white-out' and severe hypoxaemia resulting from the shunting of blood through areas of unventilated lung [164,165]. A few of these patients recover if mechanically ventilated [120,121]. Pneumothoraces may occur in patients with PCP, presumably as a result of the rupture of necrotic subpleural blebs; indeed PCP has become a leading cause of spontaneous pneumothorax in populations with a high prevalence of AIDS [90,166,167]. Small pleural effusions may also occur in association with PCP but are unusual [90, 166]. Haemoptysis and hypertrophic pulmonary osteoarthropathy are unusual associations that have been described in association with atypical histological patterns such as nodular forms with granuloma formation, cavitation, local consolidation and vascular infiltration [64,90,168,169]. Hyponatraemia as part of the syndrome of inappropriate secretion of antidiuretic hormone has been described with PCP, as indeed it has with other pneumonias [170]. Haematogenous extrapulmonary spread of *Pneumocystis* is uncommon but can occur in virtually any organ system [171]. It was found to have occurred in approximately 3% of patients with AIDS coming to necropsy at one North American centre [172].

## Outcome

Widely varying mortality rates for PCP of 5–43% have been reported in patients with AIDS [97]. Assuming a reasonable level of competence in the management of patients with PCP, mortality is chiefly influenced by the severity of the infection at presentation. This is reflected by the duration of symptoms prior to presentation (>4 weeks), the presence of tachypnoea (>30/min), the level of hypoxaemia ( $P_{aO_2} < 6.7$  kPa, 50 mmHg) and the extent of chest radiographic change [134,173]. Haematological and biochemical parameters that have been shown to predict poor outcome include a leucocytosis ( $>10.8 \times 10^9/L$ ), hypoalbuminaemia ( $<35$  g/L) or a raised serum lactate dehydrogenase ( $>300$  iu/mL) [134,173]. Mortality does not necessarily increase between the first and recurrent episodes of PCP, one cohort study of over 200 patients reporting mortality rates of 14%, 16% and 12% for the first, second and third episodes of PCP respectively [174]. Mortality is also greater in older age groups and in patients in whom pulmonary copathogens, such as bacteria, mycobacteria, *Cryptococcus* or *Toxoplasma*, are found [70,173]. The same may be true in patients receiving adjunctive steroids and from whom CMV is recovered from BAL fluid [146]. Patients who worsen after 5 days or who fail to improve after 7–10 days of treatment with appropriate medication may require treatment with an alternative drug regimen but in this group the mortality rate rises to 75–100% [97]. A prospective study of the first episode of PCP in 102 patients with AIDS found the mortality rate to be 28%, rising to 79% in those who required mechanical ventilation [173]. A relatively high mortality rate of 34% was reported in a recent retrospective survey of 116 non-HIV-infected patients with underlying diseases complicated by PCP [89]. A survival rate of 52% has been reported in a group of 29 patients who had extrapulmonary PCP [175].

# PULMONARY MANIFESTATIONS OF SYSTEMIC DISEASE

ANTHONY SEATON

Many of the diseases discussed in this book have systemic manifestations or may demonstrate a major pulmonary component of a primarily systemic disease. This chapter considers diseases primarily of other organs in which lung manifestations may occur and, in some cases, may be an important or presenting feature. For convenience, they are divided into inherited and acquired diseases, although it is clear that many in the latter category may manifest because of an inherited susceptibility, while those in the former category may also be influenced by environmental factors.

## Inherited disorders

The most important of these is cystic fibrosis, dealt with separately in Chapter 30. Less common, occurring as a potentially clinically important genotype in about 1 per 1000 Europeans, is  $\alpha_1$ -antitrypsin deficiency. Other inherited disorders are sickle cell disease (common in certain racial groups), neurofibromatosis, tuberous sclerosis, Ehlers-Danlos, Marfan and cutis laxa syndromes, Shwachman's disease and Hermansky-Pudlak syndrome.

### $\alpha_1$ -Antitrypsin deficiency

The relatively short glycoprotein  $\alpha_1$ -antitrypsin is synthesized in the liver hepatocytes [1]. The molecule is shaped like a shepherd's crook, with a reactive methionine group on an exposed part of the handle of the crook [2]. This amino acid binds tightly to protease, inactivating it. However, the methionine can be readily oxidized and inactivated itself, a mechanism that fits well with the concept that, in defending itself against attack, the lung may need to produce oxidases and also allow elastase activity to continue. However, marked overproduction of oxidases (e.g. from leucocytes stimulated by cigarette smoke or in Gram-negative septicaemia) can result in inactivation of  $\alpha_1$ -antitrypsin and other closely related enzymes such as antithrombin and complement

inhibitors, thus contributing to the severity of the disease process.

Many genotypes of  $\alpha_1$ -antitrypsin deficiency have been described but the clinically important ones in terms of lung disease are PiZZ and PiSZ [3-6]. The former results from homozygous inheritance of a gene causing substitution of a single glutamic acid responsible for the primary bend in the crook. This alters the shape of the molecule, preventing hepatocytes from transporting it into the blood. Thus  $\alpha_1$ -antitrypsin accumulates in these cells, where it may be visible as inclusion bodies and where it is probably responsible for the other serious manifestations of the disease, namely neonatal jaundice, infantile cirrhosis and a usually mild adult portal cirrhosis. The PiZZ genotype results in levels of  $\alpha_1$ -antitrypsin in the blood of about 15% of normal. The homozygote PiSS results in levels of about 60% of normal and is not usually associated with clinical disease; neither are the heterozygotes PiMZ and PiMS, which are associated with levels 60 and 80% of normal respectively. The PiS variant results from inheritance of a gene that codes for replacement of a different glutamic acid in the  $\alpha_1$ -antitrypsin molecule that acts as a signal for splicing; this substitution causes decreased synthesis of a normally functioning molecule. The PiSZ genotype is associated with levels of  $\alpha_1$ -antitrypsin of about 40% of normal and may be associated with clinical lung disease.

Details of the clinical features of  $\alpha_1$ -antitrypsin deficiency are given in Chapter 23. It is worth pointing out here that study of the biochemistry and genetics of this relatively rare lung disease has given rise to the most plausible theory of the causation of emphysema and is now leading to prospects of treatment with genetically engineered substitute antitrypsin. For the moment, however, the mainstay of management is encouragement to stop smoking.

### Neurofibromatosis

Two types of this condition are recognized, both inherited

as an autosomal dominant [7]. It occurs in about 1 in 2500 births. Perhaps half of all cases are the results of new mutations, a fact that is very important in genetic counselling. If a family have a child with evidence of the condition, they will wish to know the risks associated with a future pregnancy. If there is no evidence of the condition in other family members (and careful examination for minimal evidence is necessary), a new mutation in the child is likely. On the other hand, if other family members have evidence of the disease, there is an even chance of a further child having it. Two types are now recognized, either of which may cause thoracic spinal nerve manifestations. Type 1 is von Recklinghausen's disease and is caused by a mutation on the long arm of chromosome 17q that codes for a GTPase-activating protein known as neurofibromin [8,9]. This condition may be complicated by kyphoscoliosis, pheochromocytoma, malignant change in fibromas, pathological bone fractures and mental retardation. The type 2 disease causes mainly bilateral acoustic neuromas and other intracranial lesions such as gliomas and meningiomas, cataracts and retinal abnormalities but may involve spinal nerves. It is caused by a mutation on chromosome 22q coding for a protein called schwannomin [10].

Since incomplete penetrance is common, the type 1 gene may be expressed by a range of clinical manifestations, from a few *café-au-lait* patches (six is regarded as the minimum for diagnosis), through multiple small subcutaneous nodules, to a serious crippling condition with multiple plexiform skin tumours with gross skin thickening and involvement of the spinal canal and central nervous system. Unfortunately, the severity of manifestations in the parent is no indicator of the abnormalities to be expected in the offspring, 50% of whom are likely to show some features of the disease. Similarly, type 2 disease may present with multiple tumours early in life or in much more benign form with few lesions later in life; there is some evidence that the severity of manifestations depends on the type of mutation [10,11].

Thoracic manifestations are usually confined to chest wall neurofibromas associated with intercostal nerves and which sometimes show the dumb-bell appearance, with enlarged intervertebral foramen associated with an extension into the spinal canal (see Chapter 45). Occasionally, however, the condition is associated with diffuse pulmonary fibrosis and bullous emphysema [12], and may present as pneumothorax.

### **Tuberous sclerosis**

This condition occurs in about 1 per 10 000 births in the UK and is also inherited as an autosomal dominant, although many cases occur as a new mutation and severe disease may be transmitted by someone with minimal evidence [13,14]. Two mutations have been identified: on chromo-

some 9q encoding a protein called hamartin; and on chromosome 16p encoding tuberlin, a GTPase-activating protein [15,16]. The clinical manifestations vary considerably and are due to the presence throughout the body of abnormal hamartomatous malformations. Skin lesions (ranging from irregular depigmentation to multiple warty nodules), central nervous nodules (causing epilepsy and mental retardation) and hamartomas of kidney, heart, bone and other organs may be present. Lung lesions include multiple nodular hamartomas and a patchy fibrosis that pathologically shows associated muscle hyperplasia as well [17]. Carney's triad, i.e. pulmonary hamartomas, gastric leiomyosarcoma and paraganglioma, is mentioned in Chapter 42 [18]. Patients with diffuse pulmonary disease often present with pneumothorax. Pleural effusion has been described [19].

The diagnosis is made from the presence of typical associated lesions, especially mental retardation, the warty facial adenoma sebaceum, the yellowish rough 'shagreen patch' over the lower spine, subungual fibromas, retinal fibromas, and bone lesions showing increased radiographic density. In patients with diffuse lung disease, the prognosis is poor once symptoms are present. However, one patient has been described in whom mild stigmata of tuberous sclerosis were associated with diffuse lymphangioleiomyomatosis and who responded partially to treatment with tamoxifen [20]. Two others with a similar syndrome seem not to have responded [21]. Such treatment would be justified on a trial basis in such patients in the absence of any more promising therapy. If it were to be used, it would be of interest to look for oestrogen receptors in the lung biopsy.

### **Marfan's syndrome**

This condition is characterized by excessive height and disproportionately long limbs and digits, dislocation of the lens and cardiovascular abnormalities including aortic regurgitation, dissecting aneurysm due to medial degeneration of aorta, and mitral valve prolapse [22]. Joint dislocations may also occur in relation to lax ligaments. Like the above two conditions, it is inherited as an autosomal dominant, in this case due to a mutation on chromosome 15 that encodes the protein fibrillin, important in elastin-containing tissues [23,24]. The presentation is variable in severity but many patients die in early middle age of cardiovascular problems [25]. The manifestations of the disease result from reduced tensile strength of connective tissues in the suspensory ligament of the lens and major blood vessels.

Apart from aortic dissection and regurgitation, the thoracic manifestations are not usually very important. Scoliosis of mild degree is common but pulmonary function is generally normal when allowance is made for any spinal deformity [26]. However, pneumothorax is more common

in such patients than in the general population and both upper lobe bullae and upper lobe fibrosis have been described in patients with the syndrome. Aspergillomas may complicate bullae.

### **Ehlers–Danlos syndrome**

This is a name given to what is now known to be a group of at least nine separate inherited disorders of collagen characterized by abnormal skin, lax ligaments and hyper-extensible joints. Different types are inherited differently, although most are transmitted as autosomal dominants. It is not certain how commonly thoracic problems occur in this syndrome but haemoptysis, recurrent sinusitis and pneumonia, pneumothorax, tracheomegaly and pectus excavatum have been described more frequently than might be expected [27–29].

### **Cutis laxa syndrome**

This syndrome includes a number of inherited abnormalities of elastic tissue, characterized clinically by the development in childhood of abnormally lax and inelastic skin. The patient has characteristically loose skin around the eyes and on the ear lobes, and biopsy may show short fragmented elastic fibres with normal collagen in the skin. At least three types are recognized. The most severe is transmitted as an autosomal recessive and the skin lesion is present at birth. Severe emphysema leading to death may occur in infancy. Autosomal dominant inheritance is associated with a milder condition without pulmonary disease, while X-linked inheritance is associated with urinary tract, skeletal and joint abnormalities. Although the recessive type usually appears to be fatal in early childhood, some patients with what seems to be this variant have survived to adolescence. Severe emphysema in a child should always raise the suspicion of this condition [30–33].

### **Hermansky–Pudlak syndrome**

This is a rare condition in which albinism, a platelet aggregation defect and chromolipid inclusions in bone marrow macrophages are found [34–36]. It is inherited as an autosomal recessive. The gene has been identified on chromosome 10q and encodes a transmembrane polypeptide that is probably a component of many cytoplasmic organelles [37,38]. The patients complain of bruising, menorrhagia and bleeding after dental extraction. In a few instances, the condition has been accompanied by evidence of interstitial lung fibrosis. Accumulations of chromolipid have been demonstrated in lung macrophages, and it has been suggested that these or chronic lung haemorrhage and haemosiderosis may cause the fibrosis [39,40]. However, it seems more likely that growth factors released in the lung

may be responsible, and platelet-derived growth factor, produced by lung macrophages, has been found in raised concentrations in lavage fluid from patients with the syndrome [41].

### **Sickle cell disease**

In contrast to the other conditions in this section, sickle cell disease is very common, occurring in about 1 in 200 births in affected racial groups from West and Central Africa, Greece, Turkey, the Middle East and India. Homozygotes (sickle cell disease) inherit haemoglobin S from both parents and exhibit the disease, while heterozygotes (sickle cell trait) have a mixture of haemoglobins S and A and only show evidence of sickling when stressed by hypoxia. The full syndrome also occurs in heterozygotes having haemoglobin S combined with other variant  $\beta$ -globin haemoglobins, such as haemoglobin C or  $\beta$  thalassaemia. Haemoglobin S has a valine substituted for glutamic acid in the  $\beta$  chain due to a mutation on chromosome 11.

The homozygous disease varies in its manifestations and tends to be milder in people of the Indian races than in Africans. It is characterized by sickling crises, in which vascular occlusion, bone marrow aplasia or sequestration of blood in liver and spleen occur as a result of the deformation of red cells, and which usually present with bone or abdominal pain. Relatively frequently (in up to 20% of crises) the disease presents as an acute chest syndrome [42,43]. This typically starts with bone pain in the thoracic cage, often accompanied by pleurisy, tachycardia and tachypnoea. Inspiratory crackles and signs of consolidation tend to occur later; radiographic shadowing usually appears first at the bases and in severe cases spreads throughout the lungs. The episode is accompanied by fever and falls in haemoglobin and, in severe cases, platelet count. Pains in the abdomen and other bones may be a feature. The episode may be fatal, and pathologically the lungs show evidence of alveolar wall necrosis with obstruction of capillaries by sickled red cells [44,45]. Bone marrow and fat emboli may also be found in the pulmonary vessels.

Apart from the acute chest syndrome, patients with sickle cell disease may be at increased risk of infections [42], including pneumonia, though this diagnosis may often be made in error when infarction occurs [46]. There may also be a greater risk of pulmonary embolism in pregnancy. Heterozygotes rarely develop symptoms unless exposed to hypoxic conditions, such as in unpressurized aircraft or under unwary anaesthesia. The author has seen one such patient from the Middle East whose first crisis, induced by climbing in the Himalayas, caused ischaemic necrosis of the hips and whose second crisis occurred during surgery for that condition, resulting in pulmonary infarction (Fig. 53.1).

**Fig. 53.1** Radiographs of patient from the Middle East who developed (a) ischaemic necrosis of the femoral heads on climbing in the Himalayas and (b) infarcted lung following operation. Sickle cell trait was responsible.

For details of the management of sickle cell disease, the reader is referred to the book by Sergeant [47]. In terms of prevention of episodes, the patient should be advised about the dangers of anaesthesia and diving and the avoidance of reduced oxygen tension during climbing and aircraft flights. The chest syndrome is managed by the use of narcotic analgesics, preferably by infusion pump, intravenous fluids, oxygen and broad-spectrum antibiotics in case of infection. Exchange transfusion is used if the patient does not improve on this regimen; blood is withdrawn in 100-mL volumes and the same amount of donor blood replaced up to about 2 L in adults every day until the proportion of haemoglobin S in the patient's blood is less

than 20% [43]. This may also be used before anaesthesia for major surgery. Increasing hypoxaemia should be treated by assisted ventilation if oronasal administration is unable to provide an adequate  $F_{IO_2}$ . In desperate cases, extracorporeal membrane oxygenation has proved life-saving [48].

There is some evidence that patients with sickle cell disease develop a restrictive pattern of lung function and pulmonary hypertension as a consequence of repeated episodes of pulmonary sickling [49]. However, the assessment of lung function may be difficult because of bodily disproportion caused by disturbance of bone growth in childhood, and specific formulae for

prediction of vital capacity, total lung capacity and diffusing capacity (DLCO) in such patients have been published [50,51].

### Immune deficiency syndromes

Many inherited abnormalities of immune defences have been described. Some, such as severe combined immunodeficiency disease, present with T-lymphocyte dysfunction and infections, including *Pneumocystis carinii* pneumonia in infancy. Others, such as Shwachman's syndrome, may present in childhood with recurrent infections and pancreatic insufficiency, mimicking cystic fibrosis [52]. The hereditary antibody deficiency syndromes may present as severe episodes of recurrent infections in infancy (such as X-linked hypogammaglobulinaemia) or as a more chronic bronchial sepsis and bronchiectasis in children and adults (such as IgA deficiency). Many of these conditions may also occur as a secondary phenomenon in adult life and may be associated with chronic bronchial sepsis or susceptibility to pneumonia. For further information on diagnosis and management, the reader is referred to relevant texts [53,54].

### Niemann–Pick disease and other sphingolipidoses

These are rare hereditary diseases of sphingolipid metabolism caused by lack of specific enzymes and characterized by accumulations of abnormal lipid deposits in nervous and other tissues [55,56]. In several of them reticular radiographic shadowing on the chest film and pathological accumulations of lipid together with a fibrotic reaction have been described in the lung. Hepatosplenomegaly, mental changes, a cherry-red macula and 'sea-blue' histiocytes in the marrow are other common features. Some of these conditions occur in a mild form compatible with survival into middle age.

### Acquired disorders

#### Connective tissue diseases

Pulmonary manifestations occur frequently in the connective tissue diseases [57,58]. There is considerable overlap between the different diseases, between the associated pulmonary manifestations and between the same pulmonary conditions in the absence of obvious collagen disease. Thus classification of the disorders is rather arbitrary and is likely to remain so until their aetiology is better understood. Those considered in this chapter are summarized in Table 53.1.

**Table 53.1** Respiratory manifestations of connective tissue diseases.

### Rheumatoid disease

Pulmonary fibrosis was first described in association with rheumatoid arthritis in the late 1940s [59,60] and Caplan [61] recognized the association of arthritis and fibrotic nodules in the chest in coal-miners in South Wales in 1953. It is now clear that the lungs and pleura may manifest many different effects of rheumatoid disease and of its treatment, although all are rare except for fibrosis and pleural effusion [62].

### Pleural disease

An occasional patient with rheumatoid disease develops pleural effusion [63]. The condition is more common in men, usually in middle age, and rarely the effusion precedes evidence of joint disease. It is usually unassociated with symptoms but may cause pleurisy or, if unusually large, breathlessness. It tends to recur after aspiration. The fluid usually has a high protein and low glucose content, the latter being a useful diagnostic clue [64,65]. Another typical abnormality is a high pleural fluid/blood ratio of neurone-specific enolase, a ratio that is about unity in most conditions causing effusion but which rises to 10 or more in rheumatoid patients [66]. The effusion may appear chylous due to a high cholesterol content (Fig. 53.2). Rheumatoid factor may be present in high titre, sometimes higher than that in serum. Cytology may show large numbers of polymorphonuclear leucocytes, epithelioid cells and leucocytes containing dense granules similar to those found in joint fluid [67]. Pleural biopsy may show palisaded histiocytes characteristic of the rheumatoid nodule.

Small effusions require no treatment and may resolve

spontaneously leaving pleural thickening. Larger ones should be aspirated; if they recur, chemical pleurodesis should be carried out. Persistent effusions may cause quite extensive pleural fibrosis and restriction of lung movements, and in such cases pleurectomy needs to be considered. The efficacy of corticosteroid treatment is not established for the management of rheumatoid pleural effusion. Some patients have appeared to respond and others not; a short trial is justified in patients with disease that recurs after aspiration before proceeding to pleurodesis.

Apart from effusions, patients with rheumatoid disease quite commonly show evidence of pleural thickening or adhesions at autopsy. In some cases these may be the residua of an undiagnosed effusion. Rarely, a pulmonary nodule may cavitate and rupture into the pleural space, causing pneumothorax and bronchopleural fistula [68]. Such episodes are likely to require surgical intervention to excise the nodule and to carry out pleurodesis.

### Pulmonary nodules

Single or multiple nodules, usually about 1–3 cm in size though sometimes up to 10 cm, may appear on the chest film of patients, again usually male, with rheumatoid disease [69,70]. They are the least common lung manifestation of this disease. They tend to be subpleural in distribution and typically cavitate, leaving a very thin hair-line cavity that often gradually disappears (Fig. 53.3). Occasionally, nodules appear in patients without rheumatoid disease and on excision prove to be typical rheumatoid lesions; such patients may develop joint symptoms later [71].

There is no obvious relationship between the develop-

**Fig. 53.2** Cholesterol crystals in pseudo-chylous effusion from patient with rheumatoid disease ( $\times 350$ ).

**Fig. 53.3** Chest film of cavitating rheumatoid nodules in both upper lobes. Patient had long-standing seropositive rheumatoid disease.

**Fig. 53.4** Rheumatoid nodule showing central necrosis, a zone of palisaded histiocytes and surrounding fibrous tissue and few chronic inflammatory cells (haematoxylin & eosin  $\times 150$ ).

ment of nodules and the severity of the underlying rheumatoid disease, although there seems to be an association with the presence of subcutaneous nodules and with high titres of rheumatoid factor. Histologically they resemble subcutaneous nodules, with central necrosis surrounded by palisaded histiocytes and with a peripheral zone of chronic inflammatory cells (Fig. 53.4).

In general these nodules require no treatment, although excision is sometimes necessary because of anxiety that one might be neoplastic. As mentioned above, rupture into the pleura may cause bronchopleural fistula or be associated with pleural effusion, necessitating surgery.

The occurrence of such nodules in the lungs of coal-miners is called Caplan's syndrome [61]. At one time this strange immunological feature was thought to be a possible explanation of the development of progressive massive fibrosis. However, it is now apparent that

Caplan's syndrome is of rare occurrence in miners and is only very occasionally the cause of massive fibrosis.

### *Pulmonary fibrosis*

The best-known pulmonary complication of rheumatoid disease is pulmonary fibrosis [72–74]. Most commonly this occurs as a chronic and only slowly progressive diffuse interstitial disease, maximal in the lower zones and not causing significant disability in a patient usually handicapped by joint disease. Evidence on lung function testing of some pulmonary fibrosis may be found in 30–40% of all patients with rheumatoid disease. It is more common in men. However, this description of a relatively mild condition should not blind the clinician to other possibilities since the clinical picture extends to include an aggressive and rapidly progressive arteritic type of disease, sometimes associated with digital arteritis [75]. Anything from

this through desquamative interstitial pneumonitis to a burnt-out basal fibrosis may be seen.

Pulmonary fibrosis in patients with rheumatoid disease is indistinguishable either clinically or investigationally from the cryptogenic type, except for the necessary presence of evidence of the systemic disease. Up to one-third of patients with cryptogenic pulmonary fibrosis have positive rheumatoid factor in the absence of clinical evidence of rheumatoid disease, and it seems likely that the two conditions are both responses to the same cause [76]. What that is, of course, remains obscure. Finger clubbing occurs in about 50% of patients and repetitive inspiratory crackles are heard at the bases [77]. There is no clear relationship between the severity of the rheumatoid arthritis and that of the lung disease, although subcutaneous rheumatoid nodules are often present and the titre of rheumatoid factor may be high in patients with fibrosis [77,78].

Radiological appearances vary from an acute exudative pattern, through diffuse nodular and irregular, predominantly lower zone, infiltrates, to honeycombing (Figs 53.5 & 53.6). As stated above, the rate of progression is very variable. Little is known of the pathogenesis of the lung lesion, which represents a chronic inflammatory reaction with T lymphocytes and neutrophils [79]. Further discussion of the pathogenesis can be found in Chapter 31. The pathology is of interstitial fibrosis with some chronic

inflammatory cells [80], and bronchoalveolar lavage shows changes similar to those in cryptogenic pulmonary fibrosis. Immune complexes have been demonstrated in the lung in some cases but evidence of arteritis is usually absent [81,82].

Another, quite distinct, manifestation of rheumatoid lung disease is progressive upper lobe fibrosis and cavitation [83,84]. This may be unassociated with symptoms and present simply as an abnormal radiograph. However, bleeding from bronchiectatic cavities or infection of the damaged lung are not infrequent complications, while aspergilloma may also occur. The condition may mimic tuberculosis or other mycobacterial infection, chronic sarcoidosis or chronic allergic alveolitis and may cause diagnostic confusion if the clinician is not aware that it occurs. In one case it has been associated with bronchiolitis obliterans in the upper lobe airways, and the authors of this report suggested that this may play a pathogenic role; however, the presence of extensive rheumatoid disease in large airways in this patient may have been equally relevant [85]. A similar condition is well recognized in association with ankylosing spondylitis (see below). There is some evidence that the condition, when associated with rheumatoid disease, may stop progressing when the patient is treated with steroids, azathioprine or penicillamine [84,86,87].

Rheumatoid lung fibrosis is diagnosed when the above

**Fig. 53.5** Chest film of 60-year-old woman with mild rheumatoid disease and an acute progressive pulmonary fibrosis showing honeycombing of left lung and irregular fibrosis in right lung. There was some regression of change in the right lung after steroid therapy.

**Fig. 53.6** More chronic type of rheumatoid lung showing diffuse fine fibrosis and arthritic shoulder.

clinical features occur in a patient with rheumatoid disease. The harder one looks, the more one is likely to find evidence of disease in patients with rheumatoid arthritis, although the significance of early changes in *DLCO*, high-resolution CT or isotopic lung scans in terms of prognosis is not clear [88]. It is wise to assess the rate of progression of the lung lesion by repeating measurements of *DLCO* over several months before embarking on treatment. If no change occurs and in view of the toxic side-effects of the drugs, it is advisable simply to reassess function at, say, 6-monthly intervals and to withhold treatment. If the patient presents with evidence of more active disease, with diffuse patchy pneumonitis radiologically, or if there appears to be deterioration in lung function, a trial of high-dose prednisolone should be given, the effect being monitored by measurements of lung volumes and *DLCO*. If this is unsuccessful, consideration may be given to the use of azathioprine, cyclophosphamide or penicillamine, all of which have been used with apparent success in occasional cases, though none can be regarded as being of established value. In general, radiographic and CT changes of a fine irregular type, with loss of lung volume, indicate mature fibrosis and no response to therapy, whereas a more fluffy or ground-glass appearance may indicate more active inflammation and a better response.

#### *Bronchiolitis obliterans* (see also Chapter 29)

Airways obstruction appears to occur excessively frequently in patients with rheumatoid disease, even in as many as 30% of non-smokers with the disease [89,90]. However, in some patients a severe and rapidly progressive form of airways obstruction occurs, with widespread inspiratory crackles and often a mid-inspiratory squeak on auscultation [91–93]. The chest film may be normal or show only overinflation. Lung function shows severe airflow obstruction, a reduced *DLCO* but normal *Kco* and raised residual volume and total lung capacity measured plethysmographically; helium dilution often shows normal volumes, presumably because of inability of the gas to equilibrate with trapped air in the time available. There is a strong suspicion that in some cases the syndrome has been provoked by treatment with penicillamine [94,95] though patients have been seen who have not had this drug. The course of the condition may be progressive, with death from respiratory failure occurring within 2–3 years of onset [91]. At necropsy there is widespread fibrous obliteration of bronchioles, which are the site of an intense chronic inflammatory infiltrate. However, milder and much less rapidly progressive disease may also occur, with survival for over 10 years after the onset of symptoms [94]. There is no convincing

evidence that corticosteroids are effective in preventing progression of the condition.

### *Other pulmonary syndromes*

Pulmonary infection appears to occur relatively frequently in patients with rheumatoid arthritis [96], and the development of polyarthritis and positive rheumatoid factor has been described in patients with bronchiectasis and cystic fibrosis [97]. The significance of these observations is unclear. Conversely, bronchiectasis has been described sufficiently frequently in patients with rheumatoid disease for it to be thought that there may be a causative link or a common aetiological factor [98,99]. Chronic eosinophilic pneumonia with fever, weight loss, dyspnoea and pulmonary infiltrates has been described rarely in rheumatoid disease [100,101]; it responds to treatment with corticosteroids. Pulmonary hypertension [102,103], progressive loss of lung volume perhaps due to diaphragmatic dysfunction [104], secondary diffuse pulmonary amyloidosis [105], sclerosing mediastinitis [106] and bronchocentric granulomatosis [107–109] have all been described on rare occasions in association with rheumatoid disease. Finally, severe rheumatoid disease may affect the cricoarytenoid joints of the larynx, provoking upper airways obstruction (Fig. 53.7). One such patient treated by the author required a permanent tracheostomy.

### **Systemic lupus erythematosus**

Systemic lupus erythematosus (SLE) is a condition occurring nine times more frequently in women than in men, with a prevalence in Californian females of 1 in 700; it is also more common in the black races, being diagnosed in 1

in 245 black women in the same state [110]. The systemic features of the disease include facial rashes, discoid skin lesions, photosensitivity, hair loss, arthropathy and renal and central nervous system lesions. Diagnosis is based on the presence of such clinical manifestations together with lupus cells in the blood, positive antinuclear antibody and antibody to double-stranded DNA. The clinical spectrum of the disease is wide, varying from acute fulminant cases with widespread arteritis and renal failure to a mild condition with transient rashes and occasional systemic involvement [111]. The known causes are few; the syndrome may follow the use of certain drugs (e.g. hydralazine, phenytoin, procainamide, chlorpromazine, penicillamine) [112] and occurs to excess in patients exposed to quartz [113,114]. It is probably influenced by both genetic and hormonal factors [115], and there is some evidence of viral transmission in animals [116]; nevertheless, in most individual patients the aetiology is obscure.

As with rheumatoid disease, SLE is also associated with a wide range of pleuropulmonary complications (see Table 53.1) [117–119]. Pleurisy or pleural effusion is the most common, occurring in about half of all patients. Pulmonary infiltrates are not infrequent and may be due to primary involvement of the lung acinus by SLE, pulmonary haemorrhage, superimposed infection or infarction, or complications such as amyloidosis or lymphocytic interstitial pneumonitis. 'Shrinking lung', originally thought to be due to progressive pulmonary disease but now usually related to bilateral elevation of myopathic diaphragms, occurs occasionally.

### *Pleurisy and pleural effusion*

One of the most frequent clinical features of SLE, pleurisy and pleural effusion may be unilateral or bilateral and may occur just once or repeatedly [120,121]. Mild episodes may present with bilateral pain, a friction rub and no radiographic abnormality, or small bilateral effusions. More severe cases may be associated with breathlessness and persistent effusions (Fig. 53.8). Diagnosis is made from the clinical and haematological features of the disease. In the case of an effusion, the fluid is usually an exudate and has a normal glucose (though this may rarely be low) and a moderately high count of mononuclear or, sometimes, polymorphonuclear leucocytes. Immune complexes, reduced levels of complement C3 and C4, lupus cells and antinuclear factor may be present in the fluid. Pleural biopsy changes are usually non-specific, although fibrinoid deposition and haematoxylin-staining bodies may be seen. More usually the pleura is oedematous, infiltrated with mononuclear cells and covered with a fibrinous exudate [122].

The normal course is for spontaneous resolution, aided by aspiration. Pain may be relieved by non-steroidal anti-

**Fig. 53.7** Flow–volume loop from patient with severe rheumatoid disease and cricoarytenoid involvement showing attenuated peak flow and inspiratory flows.

**Fig. 53.8** (a) Posteroanterior radiograph of patient with systemic lupus erythematosus showing pseudotumour in right lower zone. (b) Lateral radiograph shows this to be an effusion encysted in the oblique fissure.

inflammatory drugs. In severe or persistent cases, high-dose oral steroids are usually effective. The main problem is reassuring oneself that the lesion is not due to infection or infarction, both of which occur frequently in SLE. The former may be excluded by culture of sputum, blood and pleural fluid. The latter should be suspected if the patient has the lupus anticoagulant (see below).

#### *Lupus pneumonitis*

This presentation of SLE, which occurs in some 12% of patients, usually mimics a bacterial pneumonia, the patient being ill, febrile and breathless [123–125]. Pleurisy, cough and sometimes haemoptysis may occur. Inspiratory crackles may be heard over the lung and the patient may

be hypoxaemic. Pneumonic infiltrates are most frequently bilateral and basal but may be diffusely distributed and patchy. Occasionally, however, the radiograph may be apparently normal, suggesting that the episode is largely confined to the pulmonary vessels [126]. Pleural effusions may be present also.

Diagnostic difficulty arises in two respects. If the patient was not previously known to have SLE, the episode is understandably thought to be an acute infection and the diagnosis only made after antibiotics prove ineffective, bacteriology is negative and the typical haematological features are detected. On the other hand, if the patient is known to have SLE, the problem is whether the illness is acute lupoid lung or a secondary infection. Here the tendency is to assume the former, a diagnostic decision that may literally prove fatal if the patient has pyogenic or opportunist infection. Almost one-third of patients with SLE now die of infections (see below). In this situation, careful microbiological assessment should be carried out and, if necessary, both antibiotic and anti-SLE therapy used.

Lupus pneumonitis is often a severe, potentially life-threatening, disease. Pathologically, the lungs show non-specific inflammatory changes at necropsy, including mononuclear and polymorphonuclear cell alveolitis, alveolar wall oedema and sometimes an arteritis of small vessels with lymphocytes and plasma cells. Some studies have shown alveolar deposition of immunoglobulin and the presence of antinuclear antibodies in alveolar walls and capillaries [127,128], although at present lung biopsy is not helpful in making a positive diagnosis. It may of course be useful in excluding opportunist infections.

Once the diagnosis is made, the condition should be treated vigorously. There is usually a good response to high-dose (60mg or more daily) prednisolone and this should be started immediately. If response does not occur within 2–3 days or if there is evidence of renal involvement, it would be the author's practice to add cyclophosphamide. When the patient has improved, the drugs may be slowly reduced in dosage. Lung function (volumes and DLco) and renal function should be monitored, stopping the cyclophosphamide first and reducing the prednisolone to as low a maintenance level as keeps the patient free of recurrence. Each patient needs to be treated as an individual, the dose of therapy being titrated against the clinical response; it is not possible to be dogmatic about treatment.

### *Pulmonary haemorrhage*

SLE is one of the causes of acute diffuse pulmonary haemorrhage [129–132] (see Chapter 51). The patient typically presents with malaise, cough, dyspnoea and haemoptysis, which may be no more than a little streaking of the sputum or may be massive. The chest film shows bilateral, often

quite extensive consolidation, and the diagnostic clue comes from the finding of a low haemoglobin. Clinically it is indistinguishable from Goodpasture's syndrome, although antiglomerular basement membrane antibodies are not detectable.

The condition may prove fatal despite treatment and has an approximately 50% mortality rate. Appropriate oxygenation, transfusion of blood and high-dose corticosteroid and cyclophosphamide therapy are recommended when the diagnosis is suspected. If there is doubt about the diagnosis, plasmapheresis may be tried, though the evidence in the literature suggests that this does not influence survival [132].

The pathological findings, apart from extensive alveolar haemorrhage, are of non-specific alveolitis and, in some patients, an extensive neutrophil inflammatory infiltrate of small arteries, arterioles and capillaries [132,133]. Pulmonary haemorrhage may also occur in SLE secondary to uraemia or thrombocytopenia, in which case the pathological changes are simply those of haemorrhage and haemosiderosis.

### *Chronic interstitial fibrosis*

Some evidence of chronic alveolitis is found in a majority of patients with SLE subjected to necropsy, though in some cases these may be secondary to infection or infarction, and during life abnormalities of lung function in terms of DLco and of the ratios of lymphocytes in alveolar lavage fluid are not infrequent [134]. Such findings do not necessarily indicate progressive lung disease and may regress [135]. Clinical evidence of chronic interstitial fibrosis, indistinguishable clinically, functionally and radiologically from the cryptogenic disease, is found rarely in SLE. Nevertheless, there are enough reports in the literature to make it clear that the association does occur occasionally and that it is associated with immune complex deposition in alveolar walls [136–138]. While it would be sensible practice to treat such patients with steroids and immunosuppressants after appropriate assessment of the severity and rate of progress of the disease, anecdotal reports suggest that it does not usually respond and has a relatively poor prognosis. Again, each case should be treated on its merits; it would be surprising if mild, non-progressive cases did not occur.

### *'Vanishing lung' syndrome*

These patients present with increasing exertional dyspnoea and inability to take a full inspiration when they have their chest film taken. Lung function shows a restrictive pattern but usually no abnormal auscultatory signs are present in the chest. Diaphragmatic excursion is seen to be limited on screening and transdiaphragmatic pressure may be much reduced. The condition is probably due to respiratory myositis [139–142].

Some evidence of diaphragmatic weakness or elevation has been shown to be present in up to one-third of patients with SLE being studied in hospital, and is thus a relatively common feature of the disease. In symptomatic patients, a good response with improvement in diaphragmatic function has followed treatment with prednisolone.

### *Other pulmonary syndromes*

It is quite usual to see radiological signs of linear atelectasis in SLE, often related to pleurisy, elevated diaphragms or infection [143–145]. No treatment is required except that for the primary condition. Patients with SLE are at increased risk of infection, probably largely due to the use of immunosuppressant and corticosteroid drugs; almost one-third of patients who die of SLE have evidence of serious pyogenic or opportunist infection at death [146,147]. *Pneumocystis* pneumonia, candidiasis, toxoplasmosis, aspergillosis and mycobacterial infections may be seen, as well as staphylococcal pneumonia. There is some evidence that alveolar macrophage function may be suppressed in SLE, rendering such patients more than normally liable to these infections [148].

Pulmonary embolism is a particular risk in patients with SLE with the lupus anticoagulant. This is an antiphospholipid antibody present in a small number of patients and is associated with central nervous system disease, recurrent abortions and thromboses [149,150]. It also causes a false-positive venereal disease reference laboratory (VDRL) test for syphilis. It interferes with the transformation of prothrombin to thrombin and thus causes a prolonged partial thromboplastin time. However, paradoxically, it causes an increased susceptibility to thromboses, probably as a result of its inhibition of the release of arachidonic acid metabolites from cell membranes and therefore the loss of their inhibitory effects on platelet aggregation.

Perhaps also related to the presence of the lupus anticoagulant is the development of pulmonary hypertension, which occurs in a small number of patients with SLE [151,152]; in one report, five of six patients with pulmonary hypertension had the anticoagulant. Associated vasculitis and Raynaud's disease may also be factors in the aetiology of pulmonary hypertension.

The differential diagnosis of diffuse or patchy pulmonary infiltrates in SLE should include four other possibilities: (i) some of the drugs used in its treatment (cyclophosphamide and azathioprine) may occasionally cause interstitial pneumonitis (see Chapter 55); (ii) occasionally patients with SLE develop lymphocytic interstitial pneumonia, with dense patchy infiltrates and a relatively benign course (see Chapter 40) [153]; (iii) a patient with, or even without, chronic renal involvement may rarely develop secondary amyloidosis involving the

lung parenchyma (see Chapter 51) [154]; and (iv) pulmonary oedema secondary to renal failure may also occur (see Chapter 27).

### **Systemic sclerosis**

Systemic sclerosis is a multisystem disease characterized by fibrosis of the epidermis and dermis (scleroderma), Raynaud's phenomenon and fibrosis of other organs including the kidneys, lungs, heart, gastrointestinal tract and skeletal muscles [155]. It occurs in 5–20 people per million per annum and is about three times more common in women than men. The peak incidence is between the ages of 20 and 60. There are no known geographical differences in incidence, although it does seem to be more frequent in manual workers and a number of environmental factors have been associated with an increased risk of the condition. The prognosis depends very much on which organs are involved. A relatively benign variant, scleroderma, involves only the skin, causing disfigurement and discomfort but not threatening life. However, most patients develop renal, cardiac and/or lung involvement and this reduces the 5-year survival to about 70%. One variant, known by the acronym CREST, is characterized by finger-tip calcinosis, Raynaud's phenomenon, oesophageal dysfunction, sclerodactyly and skin telangiectasis. The skin involvement is more limited, usually being confined to the face and hands, and visceral involvement occurs later or not at all. Nevertheless, lung fibrosis or pulmonary hypertension are common accompaniments eventually.

The patient with systemic sclerosis usually presents with tight shiny skin on the hands and face, often spreading eventually all over the body. The rapidity of progression is very variable and unpredictable. Renal involvement is the main cause of death. The renal lesion appears to be a vasculitis of small arteries, with endothelial swelling, intimal thickening and a perivascular cuff of mononuclear cells, leading to intimal sclerosis and fibrinoid change and secondary kidney avascularity and infarction. These changes mimic those occurring in accelerated hypertension, which is a complication of the disease, but are not secondary to it as they may be present even if the blood pressure is normal. Similar arterial and arteriolar changes are present in the skin, where a diminution in the numbers of capillaries has also been demonstrated.

The development of renal disease is of serious import, since renal failure and malignant hypertension are likely to occur and cause death within a few years. Almost equally serious is cardiac involvement, which may present as cardiac tamponade due to pericardial effusions or fibrosis, as heart failure due to patchy myocardial fibrosis (probably also related to small vessel disease) or as syncopal attacks due to cardiac conduction disturbances

[156–159]. Lung involvement is the other important cause of death [159].

Other organs that may be involved include the oesophagus (which characteristically lacks peristaltic activity, causing dysphagia and reflux), the small intestine (leading to malabsorption), the thyroid (fibrosis) and, very occasionally, the central nervous system and cranial nerves. Systemic sclerosis may also be associated with Sjögren's syndrome, primary biliary cirrhosis and other collagen diseases.

### *Aetiology and pathogenesis*

There is no strong evidence of genetic factors in the aetiology of systemic sclerosis [155,159]. On the other hand, there are several well-recognized environmental factors. The disease is more common in manual workers and has been associated with exposure to quartz in mining and quarrying and to vinyl chloride and other chlorinated hydrocarbons, and to ingestion of contaminated cooking oil in the notorious Spanish toxic oil syndrome [114,160–163]. A scleroderma-like syndrome has also been described during treatment with both bleomycin and L-tryptophan [164]. However, in most individual patients the aetiology is obscure.

Whatever the primary cause, the most obvious pathological lesions occur in small blood vessels and the organs they supply. It has been suggested that the initial damage caused by a number of different factors may be to the endothelial lining of those vessels, which in turn allows proteins and toxic substances access to the perivascular tissues where an inflammatory reaction leading to fibrosis occurs. A frequent feature of the disease, occurring in up to 90% of patients, is the finding of circulating antinuclear antibodies, usually of the speckled or nucleolar type; evidence suggests that the presence of anti-Scl 70 antibody is a strong predictor of lung disease in systemic sclerosis [165]. Further studies of the occurrence of such antibodies in populations exposed to quartz would be of considerable interest, since it is likely that they are produced in response to liberation of antigenic material from damaged cells.

### *Pulmonary fibrosis*

Most patients with systemic sclerosis and the CREST variant ultimately develop lung involvement [166,167]. Pulmonary fibrosis presents as gradually increasing dyspnoea. Cough is rarely an important symptom. Bilateral inspiratory crackles are often present but their absence is not inconsistent with the diagnosis. The radiograph simply shows fine irregular, predominantly basal, fibrosis (Fig. 53.9). In some patients dyspnoea seems out of proportion to the radiological changes, and in these individuals it is likely that pulmonary vascular disease (see

below) is the predominant lesion. As in idiopathic fibrosis, CT allows estimation of the extent and to some degree the stage of the disease [168,169].

Lung function testing in the presence of radiographic and clinical abnormalities is likely to show a restrictive pattern with reduction in *DLCO*, although this does not usually fall below about 60% of predicted values [168,170]. Not infrequently *DLCO* alone is reduced, and if this reduction is severe it again suggests vascular involvement. Gallium scans may show abnormal uptake, though this is of no diagnostic value. Bronchoalveolar lavage may show further evidence of lung inflammation with increased numbers of neutrophils and eosinophils, the former being associated with a more progressive condition [171–174].

The pathological findings are of banal alveolar wall fibrosis, predominantly in the lower zones, with relatively little inflammatory cell infiltrate. Secondary bronchiolectasis may be present. Arteriolar and small arterial narrowing by intimal thickening may be present [167,175]. Recent investigations of pathogenesis have identified increased local expression of endothelin receptors in scleroderma interstitial tissue [176]; endothelins are peptide mediators involved in regulation of cell proliferation. In addition, another mediator called tissue factor, which may be involved in fibrin deposition in the lung as it is in the clotting cascade, has been found in type II pneumocytes of patients with this condition [177]. However, the mechanisms of this and other forms of lung fibrosis remain obscure.

The presence of clinical evidence of interstitial fibrosis and reduced lung function in a patient with systemic sclerosis implies a reduced life expectancy, with about a 60% 5-year survival rate [166]. However, in general the fibrosis tends to be less rapidly progressive than the idiopathic form [178] and death is due to pneumonia or other, non-respiratory, complications of the disease [159]. Cor pulmonale is rare at necropsy.

### *Pulmonary hypertension*

In contrast to pulmonary fibrosis (but recognizing that overlap between the two conditions occurs), pulmonary hypertension is a very serious and progressive complication of systemic sclerosis, particularly in the CREST syndrome [179–181]. The patient again presents with breathlessness, but this tends to be rapidly progressive. There may be crackles in the lungs, although often there are no signs. Evidence of pulmonary hypertension, such as right ventricular heave and gallop rhythm and large jugular *a* waves, may be present. The lungs may look normal or avascular and the main pulmonary arteries may be dilated. The ECG shows evidence of right ventricular preponderance. Lung function testing shows a lowered *DLCO*, often of severe degree. Such patients are very likely

**Fig. 53.9** Chest film of patient with silicosis and massive fibrosis in upper lobes who developed secondary systemic sclerosis and fine lower lobe fibrosis related to this disease. Rib fractures at right base were traumatic.

to have the antinuclear antibody anti-Scl 70, perhaps indicative of a general tendency towards vascular damage.

Pulmonary hypertension in systemic sclerosis portends a particularly bad prognosis. The patients develop cor pulmonale and most are dead within 3 years. Widespread obliterative changes are present in small arteries and arterioles and extensive arteriovenous anastomoses may be demonstrated at necropsy.

#### *Other pulmonary syndromes*

The dysphagia and gastro-oesophageal reflux associated with oesophageal disease in systemic sclerosis may be responsible for nocturnal aspiration of stomach contents and recurrent aspiration pneumonias (see Chapter 13). The rigid skin together with involvement of the muscles of respiration may cause ventilatory failure, with a restrictive pattern of lung function; in such circumstances some reversibility of the muscle weakness may occur after treatment with corticosteroids [182]. Another, very rare, syndrome responsive to corticosteroid treatment is relapsing organizing pneumonitis, which has been described in association with the CREST syndrome and primary biliary cirrhosis [183]. It presents with breathlessness and confluent areas of consolidation on the chest radiograph. Finally,

in all patients with chronic pulmonary fibrosis there appears to be an increased risk of the development of adenocarcinoma or alveolar cell carcinoma of the lung.

#### *Treatment*

With the two exceptions mentioned above, corticosteroids do not seem to be of much value in the management of systemic sclerosis unless there is evidence of overlap with other connective tissue diseases. However, there is evidence that treatment with D-penicillamine improves prognosis, may prevent development of renal and possibly lung involvement and may improve *DLCO* [184,185]. It would now be reasonable policy to treat such patients with this drug, starting with 250 mg daily and increasing the dose every fortnight to about 1.8 g daily for 2 months, then tapering it again gradually to 500 mg daily. Treatment should be continued for about 2–5 years. Side-effects include digestive disturbances, nephropathy, rashes and bone marrow suppression, some of which may require cessation of treatment. In the absence of response, little is lost by trying immunosuppressive treatment and again uncontrolled evidence suggests that cyclophosphamide may sometimes be associated with improvement in lung function [186].

There is some largely speculative evidence that patients

with pulmonary hypertension may respond to pulmonary vasodilators if treated early enough [187,188]. Hydralazine, calcium blockers and angiotensin-converting enzyme inhibitors have been tried, generally without success. Nevertheless, in view of the poor prognosis of this syndrome, carefully monitored trials of such therapy in individual patients are justified. General measures include keeping the extremities warm, lanolin for softening the skin, metoclopramide and H<sub>2</sub> antagonists for dysphagia and reflux and, perhaps, peripheral vasodilators.

### **Sjögren's syndrome**

Sjögren's syndrome is characterized by a combination of dry eyes, mouth and other mucous membranes and lymphocytic infiltrates of salivary and mucous glands [189]. It is much more common in women and is often associated with rheumatoid arthritis, SLE, Raynaud's disease, scleroderma and other connective tissue disorders. In about 50% of cases, however, it is the only disease present and is called primary Sjögren's syndrome. It is of unknown aetiology, although there is a well-described association with HLA-DR3 and it may also occur in patients with either human immunodeficiency virus infection or graft-versus-host disease following marrow transplantation. Various other viral infections, including inevitably Epstein-Barr virus, have been suspected of causing the condition but no consensus has been reached.

When Sjögren's syndrome is combined with other diseases, the lungs may show any of the manifestations of those diseases. However, there is clear evidence that a proportion of patients with primary Sjögren's syndrome, ranging in different studies from 9 to 75%, develop lung involvement [190–192]. The variation in these estimates of prevalence probably reflects partly selection of the subjects and partly how thoroughly abnormalities have been sought. It seems likely that careful evaluation of symptoms, chest radiograph and lung function in patients with Sjögren's syndrome shows respiratory involvement to be present in the majority.

### **Pulmonary involvement**

Many patients complain of a persistent dry cough with associated dry tracheobronchial mucosa [190–193]. This abnormality may be present in isolation or combined with other pulmonary lesions and has been called xerotrachea. It is associated with impaired mucociliary clearance [194]. Airways narrowing, which may be severe enough to cause reduction of forced expiratory volume in 1 s or which may only be detectable by tests of flow rates at low lung volumes, occurs in a proportion of patients. Interstitial lung disease occurs in up to one-third of patients and may present in one of two broad groups: interstitial fibrosis or

diffuse lymphocytic infiltrates [195]. These conditions present no different clinical or pathological features from those occurring in the absence of Sjögren's syndrome, the patient complaining of breathlessness and radiography and CT showing diffuse irregular or patchy infiltrates respectively [196]. However, it should be noted that there is a well-recognized risk of the lymphocytic infiltrate in the lungs developing into a malignant lymphoma or reticulum cell carcinoma of highly undifferentiated type [197]. Not surprisingly, in view of the lack of airway secretions, respiratory infections and pneumonia occur relatively frequently in Sjögren's syndrome.

### **Treatment**

No curative treatment is available for Sjögren's syndrome and local measures may be necessary for symptomatic relief. The finding of abnormal lung function in a patient with the syndrome should prompt further investigation, but it would be wise not to rush to treatment of interstitial disease with immunosuppressant drugs until follow-up makes clear whether clinically significant progression is occurring. In most cases it is not [198]. Pulmonary infiltration by lymphocytes often responds to prednisolone if thought necessary; a dose of 60 mg daily is given until improvement occurs and then tapered to a maintenance dose [197]. Azathioprine has also been used with reported initial response [195]. It is not known whether this treatment prevents progression to lymphoma; if this tumour develops, appropriate chemotherapy is necessary.

### **Ankylosing spondylitis**

Ankylosing spondylitis is a condition in which progressive inflammation of spinal joints leads to ankylosis. It occurs predominantly in young adult males [199] and 90% of its victims carry the HLA-B27 antigen [200]. Beyond this strong genetic predisposition, the provoking cause or causes are not known. Apart from ankylosis of the spine, which may range in severity from involvement of sacroiliac joints only to development of a completely rigid bamboo spine, the joints of the chest wall, hips and knees may be involved, as may other large joints [201]. Some 20% of patients develop iritis and about 4% a proximal aortitis with aortic valve regurgitation. Amyloidosis may occasionally occur in patients with long-standing disease.

The patient usually presents with low backache, often referred down the backs of both legs, with stiffness in the mornings and on resting. The condition normally progresses only slowly and does not alter life expectancy or cause severe disability. However some patients run a more rapid course, early development of systemic signs or of limb joint involvement indicating that this is the case.

### Lung involvement

The lungs are usually only involved in patients with a long history of joint disease [202–205]. Two conditions are recognized. Firstly, if there is severe involvement of the thoracic cage, a restrictive pattern of lung function may occur and rarely this may be sufficient to cause dyspnoea. Usually, however, the function of the diaphragm allows adequate ventilation [206]. Secondly, some 1% of patients with long-standing, though not necessarily severe, disease may develop upper lobe fibrosis (Fig. 53.10). Again this is rarely progressive or disabling but provides a diagnostic puzzle if the association is not known. The author has seen it occur in a patient whose only evidence of ankylosing spondylitis was sacroiliac joint fusion and HLA-B27 positivity; others have also reported this, indicating that the fibrosis is clearly not secondary to a rigid chest wall [207]. The bronchiectasis that occurs secondarily to the fibrosis may become the seat of aspergillomas and thus the cause of haemoptysis. Locally invasive aspergillosis has been reported [208]. Colonization with *Mycobacterium kansasii*, *M. avium-intracellulare* and *M. scrofulaceum* has also been reported [205,207,209], though in such cases it would be difficult to know whether the mycobacteria or the ankylosing spondylitis are the cause of the upper lobe disease.

In general, no treatment is required for the pulmonary complications of ankylosing spondylitis. The important point is to be aware of the association with upper lobe fibrosis so that the patient is spared unnecessary treatment for tuberculosis.

### Other connective tissue disorders

Although respiratory muscle weakness and respiratory failure may occur in acute forms of dermatomyositis, direct lung involvement is rare in the dermatomyositis–polymyositis syndrome [210–212]. When it occurs, a subacute diffuse interstitial fibrosis with an active inflammatory component is usual. Often this is responsive to steroid treatment [213], although occasionally rapidly progressive fibrosis resistant to steroids and immunosuppressants may occur [214,215]. Bronchiolitis obliterans organizing pneumonia and diffuse alveolar damage have also been described [216]. Dermatomyositis is of course also one of the paraneoplastic syndromes associated with lung cancer. The pulmonary aspects of polyarteritis nodosa and related syndromes have been described in Chapter 38. ‘Mixed connective tissue disease’ is the term used to describe an illness showing features of several of the other conditions, rheumatoid, SLE, systemic sclerosis and polymyositis [217]. Not surprisingly, pulmonary fibrosis and pleurisy with effusions may be features of the syndrome, occurring in about one-quarter of the patients [218]. Management is along the lines indicated for the

individual diseases above, and there is some evidence that the interstitial lung involvement may respond to corticosteroids. Giant cell arteritis may very rarely be associated with a granulomatous interstitial pneumonitis or with involvement of intrapulmonary elastic arteries [219,220].

Behçet’s syndrome, a condition of unknown aetiology characterized by recurrent oral and genital ulceration, iritis, thrombophlebitis and arteritic lesions in other organs, occasionally involves the lung [221,222]. When it does, the lesions appear to be multiple recurrent infarcts with haemoptysis, caused by pulmonary arteritis and aneurysm formation. Haemoptysis may be fatal and anti-coagulants are contraindicated. Recommended treatment is with high-dose prednisolone and cyclophosphamide; if haemoptysis and thrombosis persist, stanozolol or phenformin have been suggested to enhance fibrinolysis [223]. The Hughes–Stovin syndrome may be a variant of this disease; it is characterized by recurrent thrombophlebitis and pulmonary artery vasculitis and aneurysm formation [224,225].

Relapsing polychondritis is a rare condition in which recurrent episodes of inflammation, probably mediated by autoantibodies, occur in cartilage [226–230]. It is sometimes associated with rheumatoid and other collagen diseases. Inflammation and destruction of ear and nasal cartilage, episcleritis and laryngotracheobronchial damage may occur. The latter results in airway involvement by inflammatory cells, destruction of cartilage, narrowing of the lumen and increased collapsibility. The patient complains of breathlessness and stridor may be audible. The progress of the condition may be slowed by high-dose corticosteroids, but once tracheal narrowing has occurred by fibrosis the patient is likely to suffer recurrent respiratory infections and increasing breathlessness.

### Some other systemic disorders with lung involvement

#### Rheumatic fever

Apart from the acute pulmonary effects of heart failure during rheumatic fever, a specific pulmonary infiltrative condition, rheumatic pneumonia, may occur. The patient complains of cough, dyspnoea and pleurisy and there may be haemoptysis. The radiograph may show patchy mottling or appearances suggestive of pulmonary oedema. The pathological lesions are patchy, and include alveolar wall infiltration with leucocytes, capillary endothelial necrosis and intra-alveolar haemorrhage and exudation [231]. Hyaline membranes have been described and organization with fibrosis may occur. Corticosteroids are recommended for treatment on an anecdotal basis.

(a)

(b)

**Fig. 53.10** (a) Upper lobe fibrosis with elevated hilar shadows in man with (b) sacroiliac ankylosis.

### Syphilis

Diffuse consolidation of the lung may be a feature of fatal congenital or of tertiary syphilis [232–235]. Gummas may occur in trachea, bronchi or lung, where their diagnosis nowadays is a matter of considerable surprise to the pathologist examining a biopsy or specimen of lung removed under suspicion of being a carcinoma. Diffuse pulmonary fibrosis, cavitation and bronchial stricture have been described. The offending organism, *Treponema pallidum*, is sensitive to penicillin.

### Ulcerative colitis

Minor abnormalities of pulmonary function, often of an obstructive type, are quite frequent in ulcerative colitis [236], although the disease may also be associated with lung disease separate from the well-known association of alveolitis with sulfasalazine (sulphasalazine) treatment (see Chapter 55). Most commonly there appears to be an inflammatory reaction affecting the airways, which may simply cause a persistent cough or may present as bronchiectasis or bronchiolitis obliterans [237–241]. In some patients the condition has presented as a progressive bronchiectasis following colectomy. It is distinct from smoking-related bronchitis and is well described in non-smokers. The pathological changes are basal cell hyperplasia, basement membrane thickening and submucosal inflammatory cell infiltration. Although the aetiology is obscure, it is likely that the disease represents a bronchial reaction to whatever environmental or immunological factor is causing the colitis. Interestingly, there is evidence of response to corticosteroids, either inhaled or systemic, unless there is a marked infective element [239]. There is also a report of an acute interstitial pneumonitis in association with ulcerative colitis and pyoderma gangrenosum, also responsive to corticosteroids [242].

### Crohn's disease

Occasionally Crohn's disease, or regional enteritis, coexists with sarcoidosis, although despite the histological similarities between the two conditions this is very rare [243]. Apart from this, there are reports of interstitial lung disease, lung functional abnormalities and airway inflammation in association with Crohn's disease in both adults and children [239,244,245], though this appears to be less common than with ulcerative colitis. Amyloidosis involving the lungs may also occur [246].

### Coeliac disease

There seems to be a complex relationship between coeliac disease and interstitial lung disease [247–251]. Occasionally, a syndrome of lung restriction indistinguishable from

idiopathic fibrosis has been described in patients with coeliac disease. Moreover, it has been suggested that coeliac patients may be at excess risk of bird fancier's lung, although it should be noted that they often have bird antibodies in their blood derived from eggs in the diet and distinct from the true avian antibody associated with bird fancier's lung. It seems likely that there is a true but rare association of interstitial fibrosis with coeliac disease, the aetiology being obscure.

### Whipple's disease

This condition of arthritis, weight loss, fever and steatorrhoea is characterized by fat-filled foamy macrophages and sarcoid-like granulomas in the intestinal wall and other affected tissues. It occurs mainly in middle-aged men and is caused by a Gram-positive bacillus also called after Whipple [252]. Some patients have been described as having patchy interstitial lung infiltrates and restrictive lung function [253].

### Acute pancreatitis

Pleural effusion is a well-recognized accompaniment of acute pancreatitis (see Chapter 43). A proportion of patients acutely ill with pancreatitis may develop adult respiratory distress syndrome, and it is thought that this is due to release of inflammatory mediators in ascitic fluid that induce production of interleukin 1 and tumour necrosis factor in the lung [254,255]. Circulating pancreatic enzymes themselves may also be relevant and the author has seen one patient develop rapidly progressive lower zone emphysema after an acute attack of pancreatitis associated with very high amylase levels.

### Waldenström's macroglobulinaemia

This is a condition akin to myeloma that occurs predominantly in elderly males and which is characterized by malaise, a bleeding tendency, hepatosplenomegaly and the presence of a paraprotein, usually IgM, in the blood. It generally runs a benign course. However, these patients are liable to pulmonary infections and occasionally present with pulmonary infiltrates of lymphoid or plasma cells, showing characteristic staining for the paraprotein [256,257]. In such cases, treatment with chlorambucil, melphalan or cyclophosphamide may be successful.

### Renal dialysis and transplantation

Patients being treated for renal failure and those on immunosuppressants are at increased risk of pulmonary infection [258–262]. Patients on long-term dialysis may develop metastatic calcification and this has been reported

to involve the lung to sufficient degree to cause respiratory failure and death. The patient presents with increasing dyspnoea, usually starting some months after the start of dialysis, and very fine pin-point shadowing may be visible on the chest film. It has also been described in patients after successful renal transplantation. CT and radiophosphate imaging provide useful methods of diagnosis when, as is often the case, the chest radiograph shows non-specific shadowing. The mechanism is usually thought to be deposition of calcium magnesium phosphate in the lungs as a result of secondary hyperparathyroidism due to low levels of 1,25-dihydroxyvitamin D<sub>3</sub>, with reduced renal phosphate excretion. However, this seems unlikely to be

the case in patients with successful renal transplants, in whom the mechanism remains obscure.

### Neuromuscular disease

A wide variety of neuromuscular diseases, including muscular dystrophies, Parkinson's disease and myxoedema, may cause ventilatory insufficiency leading to recurrent infections through failure to clear secretions and to chronic respiratory failure. In selected patients, management has been much improved by domiciliary ventilatory support (see Chapter 58). These conditions are discussed in Chapter 45.

# OCCUPATIONAL LUNG DISEASES

ANTHONY SEATON

Most of the diseases with which this book is concerned are probably caused by the inhalation of harmful matter, be it microorganisms, tobacco smoke, allergens or other particles. While these broad classes of substances may be encountered in the general environment, many of them occur also in the workplace in greater amounts as a result of industrial processes; a broad range of lung reactions may therefore occur as a result of workplace exposure.

## Historical aspects

It is likely that humans have suffered from occupational asthma since the change from hunting to agriculture as a means of providing food. However, the first recorded mention of breathlessness among handlers of grain was by Ramazzini, the father of occupational medicine, in 1713 [1]. The harmful effects of mining probably also date back to prehistory, when humans first started to dig underground for flints to make arrowheads and axes and thus exposed themselves to quartz dust. Certainly in Roman times it was recorded that mining was a dangerous trade, fit only for convicts and slaves. In 1556 Georgius Agricola [2] recorded the dangers of suffocation underground due to toxic fumes and pointed out that breathlessness due to inhalation of dust resulted in the premature death of many miners. However, these early accounts appear to have been sporadic and it was not until the Industrial Revolution in Britain that the coincidence of increasing amounts of occupational disease and adequate medical and scientific expertise allowed rapid progress to be made in their understanding. The diseases that came to attention at this time, in the eighteenth and early nineteenth centuries, were those afflicting knife grinders, pottery workers, coal-miners and stonemasons, the classical mineral pneumoconioses. By the middle of the nineteenth century, silicosis had been differentiated from tuberculosis [3] (which was of course rife in the new industrial cities at that time) and a peculiar black pigmentation of the lungs had been described in Scottish coal-miners [4]. Occupational exposure was also known to cause asthma occasionally [5].

In 1775, before the earliest descriptions of pneumoconiosis, cancer of the skin had been recognized by Pott as an occupational disease in the apprentices of chimney sweeps [6], and lung cancer was first described as an occupational disease in German metal miners in 1879 [7]. Indeed, it was as a result of the recognition that occupational factors were relevant to the genesis of cancer that scientists first started to study this disease and its mechanisms.

The twentieth century has seen an increasing recognition of the many lung diseases that can be caused by exposure to harmful substances in the workplace. Increasing use of asbestos from about 1900 until the middle of the century was clearly shown to be related to pulmonary fibrosis in 1930 [8], bronchial carcinoma in 1949 and mesothelioma in 1960 [9,10]. A range of other lung carcinogens, including radiation, arsenic, nickel, chromates and halo ethers, was described. The first of many causes of allergic alveolitis, inhalation of mouldy hay, was recorded in 1932 [11], and subsequently many other causes of this disease and of occupational asthma have been recognized. Berylliosis was described first in Germany in 1933 and in the USA in 1943 [12,13]. The public has been made dramatically aware of possible workplace hazards by a series of horrifying episodes of industrial gassings, the worst of which killed many thousands of people living around Bhopal in India in 1985, when a cloud of methyl isocyanate escaped from a factory producing pesticides [14].

## Types and frequency of disease

It is now clear that many of the broad types of bronchopulmonary disease may be caused or made worse by exposure to harmful substances in the workplace. Thus pulmonary fibrosis may result from exposure to asbestos or quartz, pulmonary oedema and bronchiolitis from inhalation of toxic gas, allergic responses from exposure to organic dusts and some chemicals acting as haptens, pleurisy from inhalation of asbestos, cancer from a range of carcinogens, and infection from workplace exposure to

microorganisms. The workplace may be only one factor in the causation of some of these conditions, which are discussed in more detail elsewhere in the book. A summary of lung responses to workplace hazards is given in Table 54.1.

It is difficult to know how widespread occupational lung disease is, even in advanced nations. Data obtained from workman's compensation and disability awards are likely to include only cases that fulfil quite strict criteria for diagnosis, usually from a rather selective list of conditions. Similarly, data from statutory notifications of disease are only representative of those required to be notified and again are often the tip of an iceberg. On the other hand, surveys of population samples are likely to have to rely largely on self-determination of the causes of illness and therefore probably overestimate prevalence. In the British Labour Force Survey of 1990, which questioned a random sample of the workforce in 60 000 households, some questions were added about occupational disease. The response indicated that of a workforce of about 20 million, some 30 000 people had asthma and 60 000 had other lung disease that they attributed to their work, in addition to a substantial number who thought that their lung disease was made worse by their work [15]. While these figures probably represent an overestimate, they should not be dismissed lightly, since patients often discover the relationship of their illness to work before their doctors. It might be argued that patients in general have an unsophisticated concept of disease causation, but often so do doctors. In particular, clinicians have a marked tendency to attribute disease to one cause, when epidemiology teaches that with most diseases there are multiple possible aetiological contributors. For example, it is usual

to attribute lung cancer or chronic airflow obstruction to smoking if the patient does indeed smoke. However, many epidemiological studies have shown that workers in a number of dusty industries have an increased risk of one or other of these diseases compared with non-exposed people of the same smoking status. Thus, although it can never be proved in an individual case with clinical certainty, in a population of dust-exposed workers there may be individuals who would not have developed disabling lung disease had they not been exposed to the workplace hazard. Who is to say that such people are wrong in attributing their illness to work rather than cigarettes when it is likely that both have played a part?

Perhaps the best information currently available comes from the UK SWORD survey, in which occupational and chest physicians report cases of what they think are occupationally caused lung disease on a regular and confidential basis [16,17]. Although almost certainly giving an underestimate because of failure to sample all those doctors who see such patients, this allows some estimate of incidence of such diseases to be made. Results from recent surveys have shown, as expected, that asthma and mesothelioma rank as the most commonly recognized conditions, being reported in about 950 and 650 patients each year respectively. There are good reasons to believe that the true incidences of these conditions in the UK are approximately 3000 and 1000 respectively. Two other conditions are apparently more common than was originally anticipated: acute inhalation injury, which is reported in about 300 people each year, and the syndrome of bronchial hyperreactivity following such exposures, sometimes called reactive airways dysfunction syndrome. The latter condition is responsible for a proportion, as yet undeter-

**Table 54.1** Lung responses to workplace hazards.

Type of disease	Postulated mechanism	Typical exposure
Diffuse fibrosis	Macrophage-mediated Delayed hypersensitivity	Asbestos Beryllium
Nodular fibrosis	Macrophage-mediated	Quartz, coal
Emphysema	Neutrophil elastase release	Coal, cadmium
Chronic bronchitis	Airway inflammation	Dusts and fumes
Acute bronchitis	Airway inflammation	Irritant gases and fumes
Airway hyperreactivity, bronchiolitis obliterans,		
Asthma	Airway hypersensitivity	Flour, wood, isocyanates
Byssinosis	Endotoxin complement activation	Cotton dust
Allergic alveolitis	Complement activation Cytokine release	Thermophilic actinomycetes
Bronchial carcinoma	DNA damage	Asbestos, chloromethyl ether
Pleural mesothelioma	DNA damage	Asbestos

mined, of reports registered under both asthma and inhalation injury categories. It is likely that the same relative frequencies of different occupational lung diseases as reported in SWORD are present in other industrialized countries, although the actual numbers will differ in relation to the efforts made nationally to prevent them.

## Deposition and clearance of particles

The details of the lung's defences are described in Chapter 4. In brief, the harmfulness of an inhaled particle depends on its inherent toxicity, its ability to penetrate to the site at which it can exert its effects and the amount retained in the lung. Penetration depends on the ability of the particle to overcome the physical forces tending to bring it into contact with the walls of the airways, namely sedimentation, impaction, interception, diffusion and electrostatic precipitation [18].

1 Sedimentation, or movement under the influence of gravity, proceeds at a rate that depends on the density and the square of the diameter of the particle; thus large dense particles fall rapidly and are deposited primarily in the nose, mouth and larger airways.

2 Impaction occurs when a particle fails to follow a change in direction of airflow and strikes the airway wall; it depends on the particle's momentum (the product of mass and velocity) so again large particles are filtered out by the larger airways.

3 Interception is a factor in the deposition of fibrous aerosols, when the ends of long thin particles strike the airway wall.

4 Diffusion occurs as a result of Brownian motion, due to bombardment of very small particles by gas molecules in the air, and is particularly important with respect to deposition on alveolar walls of particles of less than  $0.5\mu\text{m}$ . It is also the mechanism whereby inhaled toxic gases exert their effects on the airways and alveoli.

5 Electrostatic precipitation was until recently not thought to be important because of the conducting properties of mucus. However, studies in rats have shown considerably greater lung retention of highly charged compared with uncharged particles, suggesting that the effect of charge may be pathologically significant [19].

An indication of the likelihood of a particle's deposition in various parts of the respiratory tract in relation to its aerodynamic diameter, i.e. its diameter expressed in terms of it behaving as a sphere of unit density, is shown in Fig. 54.1 [20]. Another representation of lung deposition patterns is given in Fig. 54.2, which shows that the highest rate of alveolar deposition occurs with a particle size around  $0.02\text{--}0.06\mu\text{m}$  ( $20\text{--}60\text{nm}$ ). This is the size range of particles in fume and in the nucleation mode of ambient air pollution [21].

Fig. 54.1 Fractional deposition in different parts of the respiratory tract of particles of differing aerodynamic diameters. (From Emmett *et al.* [20].)

Knowledge of the physical behaviour of particles in the respiratory tract is particularly important in the design of dust-sampling instruments. These play a crucial part in monitoring the exposure of workers to aerosols in the workplace and, increasingly, in measuring exposures as part of epidemiological studies aimed at producing information about exposure-response relationships on which preventive action can be based (see Chapter 3). Such instruments are now available that can measure 'respirable' particles ( $<7\mu\text{m}$ ),  $\text{PM}_{10}$  ( $<10\mu\text{m}$ ) (Fig. 54.3) [22] and 'inspirable' particles that closely resemble in size those passing into the human nose and respiratory tract [23]; others can fractionate a mixed dust cloud into particles of different aerodynamic sizes. All these instruments allow the dusts to be weighed. However, not yet available is a simple method for measuring asbestos or other fibres in the air. These still have to be collected on a filter and then counted, a laborious and rather unreliable procedure [24].

Once deposited in the respiratory tract, the fate of a particle depends on the body's clearance mechanisms and on its ability to resist them. Larger particles, deposited on the airways, are generally cleared efficiently within 24 h by the mucociliary mechanism, though such clearance may be prolonged if the airways are damaged by cigarette smoke or fume inhalation [25,26]. Such cleared particles are either coughed up or swallowed. Particles reaching the acinus are beyond the region of cilia and production of mucus

**Fig. 54.2** Lung deposition and particle size: highest rate of deposition occurs with submicrometre-sized particles. (From Committee on the Medical Effects of Air Pollutants [21] with permission.)

and are cleared much more slowly [27]. Deposition occurs predominantly at bifurcations of alveolar ducts [28]. The mechanism of particle removal involves ingestion by alveolar macrophages [29] or type I alveolar epithelial cells [30]. Having ingested a particle, the type I alveolar cell either delivers it into the interstitial space of the alveolar wall, where it can be taken up by interstitial macrophages or flow with interstitial fluid into the lymphatics, or dies and passes into the alveolar lumen [31]. The macrophage also seems to have several options: it may migrate up to the mucociliary escalator, perhaps impelled by a flow of alveolar surfactant; move to the terminal airways due to a viscosity gradient [32]; or may pass between the alveolar epithelial cells, presumably temporarily unlocking the tight junctions by proteolytic enzyme action, into the interstitial space. It may then proceed into the lymphatics to pulmonary and hilar nodes, or pass back into the airways at the end of the terminal bronchiole, through lymphatic sumps [30]. It seems likely that all these mechanisms operate, though their relative importance has not been established. It is probable that alveolar clearance occurs over a prolonged period, the first particles being removed within 24 h but many remaining for months and even years [33]. The presence of dust pigment around the centre of the acinus is of course a finding familiar to all pathologists.

The harm exerted by the particle once inhaled depends on its biological, chemical and physical properties, and on the amount inhaled. Biological factors include its ability to

act as a sensitizer or to overcome attack by macrophages, for example allergens such as grass pollen (up to 100 μm in diameter) provoke a primarily nasal reaction of a hypersensitivity type, while mycobacteria cause alveolar disease by being resistant to killing by macrophages. Chemical factors include the effects of gases or particle surfaces on cell or lysosomal membranes, for example the cytotoxic effects of sulphur dioxide and quartz. Physical factors apply when the particle is too large to be removed, as with asbestos fibres which are only partially ingested by macrophages. In addition, recent studies of microfine particles of less than 50 nm diameter have shown paradoxical toxicity in rats at inhaled concentrations too low to cause pathological effects when the same concentration is inhaled in the form of larger, micrometre-sized respirable particles [34]; this strongly suggests that physicochemical factors associated with particle surfaces may be responsible for toxicity in particles associated with air pollution and fumes such as those derived from welding and metal cutting [35]. Finally, the total mass of dust inhaled is clearly important, in that the lung's defences presumably evolved to enable removal of the modest amounts of particulate matter found in the ambient air (mainly bacterial, fungal and floral) and not the large amounts of inorganic matter that may be inhaled in the workplace. Nevertheless, a measure of the efficiency of these mechanisms is that a coal-miner may easily inhale 4 kg of coal dust in a lifetime but at death only about 10–30 g remain in the lungs [36].

## Mineral pneumoconioses

The term 'pneumoconiosis' was coined by Zenker [37] to define a group of diseases caused by inhalation of dust. It usually implies a tissue reaction within the lung to the dust and, while strictly including diseases due to organic dusts, is generally used in relation to diseases and radiological abnormalities caused by mineral dusts. The most common pneumoconioses are coal-workers' pneumoconiosis, silicosis and asbestosis, although very many other types have been described, usually due to inhalation of mixed dusts containing silicates. They range in seriousness from asbestosis, which not only causes diffuse fibrosis but also increases substantially the patient's risk of lung carcinoma, through silicosis that causes progressive patchy nodular fibrosis, to conditions such as stannosis, siderosis and baritosis, which simply cause radiological change without physiological effects.

The inhalation of mineral dust may also have effects other than leading to pneumoconiosis, such as carcinogenesis and initiation of bronchitis or emphysema. These effects are discussed in subsequent sections.

## Coal-workers' pneumoconiosis

### Epidemiology

Coal-workers' pneumoconiosis is virtually confined to underground coal-miners, though it may occur in any place where a worker is exposed to high levels of coal dust in poorly ventilated conditions. Thus it has been described in coal trimmers, loading coal in the holds of ships, and in men and women sorting coal on surface screens. Coal is usually mined underground by one of two methods, long wall or room and pillar. In the former, used widely in Europe, all the coal in a seam is taken in a series of cuts by a machine across a face of up to 200m. The roof above, usually composed of quartz-bearing rock, is supported by a row of hydraulic supports that are advanced after each cut, allowing the roof behind to fall in. The faceworkers operate the coal-cutter and roof supports in the tunnel along the face, which is ventilated by air blown down an access tunnel (roadway), across the face and out through a return roadway. The height of the face may vary from 46 cm to 2.5–3m, depending on the height of the coal seam. Dust is generated largely by the coal-cutter but also by the movement of roof supports, by the collapse of the roof as these are moved forward, and by the transport of coal from the face. As the face progresses into the coal seam, so the roadways at either end are driven forward through coal as well as through the rocky strata. This may be done by powerful drilling machines, by placing and firing explosives or by other traditional tunnelling methods, all of which generate dust.

Room and pillar mining is used more widely in the USA. It involves driving a series of tunnels into the coal seam and linking them by cross-tunnels, leaving square pillars of coal to support the roof. Additional support is given usually by roof-bolting, where loose strata above the coal are fixed by drilling a bolt through them into firmer rock above. This form of mining is the more traditional and is used when there is sufficient coal for it to be economical to leave the pillars. It is the method widely used in mining for many other minerals.

From this brief description, it can be seen that miners may be exposed to dust not only from the coal seam but also from roof, floor and intrusions of rock (dirt bands) into the seam. Miners driving the roadway (known as hardheaders, tunnellers, rippers and brushers in different mining areas) are likely to be exposed to a mixture of mineral dusts. Other underground workers are also exposed to the same dusts, though generally more diluted, in the return roadway as well as to dust generated at points where coal is tipped from one transportation system (conveyor belt or bogie) to another. Therefore even miners working in the same colliery may show different types of pneumoconiosis depending on the work they do. It should be noted that ventilation of a mine by blowing air

in one end and out the other across a long face wall does not adequately ventilate blind tunnels off the main airstream. In room and pillar mining, curtains (brattices) are hung in appropriate places to direct the flow of air away from the area where dust is being generated. In blind tunnels, forced ventilation or extraction by ducting is necessary. Again, absence of these provisions puts some men at greater risk than others.

Understanding of coal-workers' pneumoconiosis is complicated further by the fact that coal and coal dust differ dramatically from place to place. Some coals, formed under very high pressure, are particularly hard and very high in carbon content (and therefore combustibility), anthracite being the hardest of these. They are known as high-rank coals. Softer bituminous and steam coals leave more ash when burnt and are said to be of lower rank. The ash remaining in the fireplace or a coal-fired boiler is a mixture of quartz, kaolinite, mica and other silicate minerals. These are also present in the dust the miner inhales and in the lungs at postmortem, influencing the risk of pneumoconiosis and the type of pathological reaction.

Immediately after the Second World War, some 3000 men per annum were being diagnosed as having coal-workers' pneumoconiosis in the UK [38]. The realization of this epidemic led to a series of investigations by the Medical Research Council and the National Coal Board that have gone a long way to understanding the epidemiology and aetiology of the disease [39,40]. These studies have shown that the risk of pneumoconiosis varies considerably from place to place, roughly in relation to the rank of coal, high ranks being the most dangerous [41]. They have also demonstrated a relationship between a miner's exposure to respirable dust and risk of disease (Fig. 54.4); the mean of these relationships in different collieries has been used as information on which to base dust standards for protection of the workforce in coal-mines [42,43]. Other studies have shown relationships between exposure to relatively high levels of quartz in the dust and rapidly progressive pneumoconiosis or probable silicosis [44], and between dust exposure and the risks of bronchitis and emphysema [45–48]. In the UK, this information has been used by the coal industry as a basis for preventive measures and each year very few active miners are diagnosed as having pneumoconiosis; increasingly these are older men, coal-workers' pneumoconiosis in this country being a rare disease in miners under the age of 50 [49]. The disease does of course occur throughout the world, wherever coal is mined. In western Europe and the USA in general, measures of dust control have resulted in a decreased prevalence of disease, although in newly emerging industrial nations such as China and India it is likely that new cases will be seen frequently unless appropriate preventive measures are taken.

Fig. 54.4 Risk of category 2 simple coal-workers' pneumoconiosis in relation to average dust exposure over a working lifetime.

## Clinical features

### Chest radiography

The earliest sign of coal-workers' pneumoconiosis is nodular shadowing on the chest radiograph. These appearances are usually classified according to the International Labour Office (ILO) standard classification, which is described in Chapter 3 [50]. The nodules are most commonly of the q type (1.5–3 mm in diameter), though p (<1.5 mm) and r (>3 but <10 mm) lesions may occur, and it is quite usual to see examples of at least two of these types in any one miner's film. They are usually more profuse in the upper and middle zones. The profusion of nodules (categories 1–3) is an indirect measure of the miner's exposure to respirable dust and thus increases with increasing exposure, although progression of the p and q types does not occur after dust exposure has ceased. There is evidence that the larger nodules, which are usually relatively sparse, result from quartz exposure and represent silicotic nodules pathologically [36,51]. They may progress both in size and profusion after exposure has ceased. The very small p lesions seem to be related to the combination of pneumoconiosis and emphysema, while the q lesions represent overlapping coal macules [36]. Very rarely, the onset of severe emphysema may result in obscuration of rounded opacities, although spontaneous regression in the absence of emphysema does not occur in true coal-workers' pneumoconiosis. These distinctions between the radiological types of the condition are far from clear-cut since there is considerable interobserver and intraobserver variation in classifying films according to type of opacity. Typical examples are illustrated in Fig. 54.5.

**Fig. 54.5** Simple coal-workers' pneumoconiosis: (a) type p, pinpoint opacities; (b) type q, micronodular opacities; (c) type r, nodular opacities typically associated with quartz exposure.

The early nodular lesions are frequently accompanied by Kerley B lines. However, it has been recognized that coal-miners also develop other small irregular and linear shadows on their radiographs, similar to those occurring early in asbestosis [52]. These tend to occur more at the lung bases and to be of relatively low profusion, rarely more than category 1. There is evidence that their prevalence is related not only to exposure to respirable dust but also, unlike the rounded opacities, to age and cigarette smoking [53]. Pathologically and physiologically they seem to be related to the presence of emphysema

and airflow obstruction [52], and it is likely they represent paraseptal deposition of dust and the pathological reaction to it. There is no evidence that they are relevant to subsequent risks of progressive massive fibrosis (PMF).

The above description applies to simple coal-workers' pneumoconiosis, a condition in which only small opacities are present. However, a proportion of coal-miners develop so-called complicated pneumoconiosis (because originally it was thought that this was a consequence of complication of simple disease by tuberculosis) or PMF

[54,55]. This condition presents as a larger shadow, equal to or greater than 1 cm in maximum diameter, often initially in the right upper zone (Fig. 54.6). The lesion gradually grows, becomes more radiodense and causes distortion of adjacent lung and bronchi often with bullous emphysema. Frequently similar lesions appear in other parts of the lung and run a similar course. The course is very variable and often becomes arrested at a relatively early stage, although in some cases both lungs ultimately may be almost completely replaced by PMF and emphysema, with resultant cor pulmonale.

While a miner with a high category of simple pneumoconiosis is at greatest risk of developing PMF, it is now clear that simple pneumoconiosis need not be visible on a radiograph for PMF to occur [55]. Although simple pneumoconiosis does not normally progress or regress after dust exposure ceases, it has been shown that PMF commonly occurs after the miner has left the industry, sometimes as much as 20 years later [55]. This interesting fact suggests strongly that simple pneumoconiosis and PMF may be two separate diseases, both related to dust exposure. This is discussed further in the section on pathogenesis.

Massive fibrosis may present several different radiological appearances, of which at least two are relatively common and easily distinguished [56]. The most frequent appearance is as described above, initially rather indistinct and ovoid and gradually becoming more clearly demarcated and larger. This is particularly common in areas where high-rank coal is mined. The other type seems

to result from aggregation of the larger r-type nodules to give a multinodular appearance initially, though ultimately this may come to resemble the other type. These appearances seem most common in miners exposed to high levels of quartz [56,57].

A few miners, especially those with rheumatoid arthritis or with rheumatoid factor in their blood, develop well-defined rounded lesions that grow to about 2–3 cm in diameter or rarely somewhat larger (Fig. 54.7). They are usually multiple and have a marked tendency to cavitate. They often occur on a background of no simple pneumoconiosis and in miners with a relatively low dust exposure. They are called Caplan's lesions and their combination with rheumatoid disease Caplan's syndrome, after the Pneumoconiosis Panel doctor who described them [58–60]. They do not have an ominous prognosis and cause no significant functional impairment, being unassociated with emphysema [61].

### *Symptoms and signs*

The miner with simple coal-workers' pneumoconiosis has no symptoms or signs attributable to the disease. This is a particularly important fact, not always appreciated by doctors tempted to link radiological abnormality (which may be extensive) with symptoms. This is not to say that miners with simple pneumoconiosis may not become breathless; they may and often do, but this is due to some other disease such as asthma, emphysema or heart failure. Failure to appreciate this may result in the patient not

**Fig. 54.6** Coal-workers' pneumoconiosis: extensive (category 3) simple pneumoconiosis with early massive fibrosis (stage A) in right upper zone.

**Fig. 54.7** Multiple rounded lesions of Caplan's syndrome in coal-miner with rheumatoid disease.

receiving treatment appropriate to the condition, sometimes for years. It is particularly unfortunate if this results in treatable conditions such as asthma being missed. Nevertheless, miners develop emphysema more often than other groups of workers with similar smoking habits, and this has also been shown to be related to their exposure to respirable dust [48] (see Pathogenesis).

The early stages of PMF likewise are insufficiently extensive to cause any symptoms or dysfunction. However, as the disease progresses the combination of the fibrous masses and the associated emphysema leads to increasing breathlessness. Cough is not typically a feature unless there is considerable bronchial distortion, and the breathlessness is unvarying and related to exertion. Ultimately the patient reaches the stage of hypoxic and often hypercapnic respiratory failure and cor pulmonale [62,63]. Mortality studies of coal-miners have emphasized their increased risks of dying of chronic bronchitis and emphysema, as well as pneumoconiosis [64].

There are certain other negative features of coal-workers' pneumoconiosis apart from absence of symptoms in the simple disease. These are an absence of physical signs (clubbing and crackles are not features), no increased risk of bronchial carcinoma [64,65] and no increased susceptibility to tuberculosis. However, coal-miners do run an increased risk of gastric carcinoma [64], for unknown reasons (although the author is inclined to

speculate that this may be related to exposure to water underground containing *Helicobacter pylori*), and seem to be unusually susceptible to infections with opportunistic mycobacteria [66] (perhaps for the same reason).

### Lung function

Several studies have indicated that coal-miners have somewhat lower forced expiratory volume in 1 s ( $FEV_1$ ) than control groups but that  $FEV_1$  does not decrease further in relation to increasing radiological category of pneumoconiosis [67,68]. This, together with the epidemiological demonstration of raised residual volume in coal-miners that increases in relation to category of pneumoconiosis [69], is consistent with the hypothesis that coal dust has an effect on airways or alveoli separate from the effect by which it causes pneumoconiosis. Studies on small numbers of miners with high categories of simple pneumoconiosis have shown changes in lung mechanics suggestive of either small airways disease or patchy emphysema [70,71]. However, in general it may be assumed clinically that a miner with simple pneumoconiosis, and without complicating chronic airways disease or emphysema, has an  $FEV_1$  and forced vital capacity (FVC) within the normal range. Diffusing capacity is also usually normal, though slight reduction may be associated with the p type of opacities, and this has been

taken to indicate that emphysema coexists with these lesions [72].

PMF may also be present without functional abnormalities. However, as the condition progresses and particularly if emphysema develops, function becomes impaired by a mixture of restriction of lung volumes and airflow obstruction [73]. Which of these is dominant depends on the size of the masses and the amount of emphysema, although severe airflow obstruction is a common feature in the late stages as a result of reduction in retractive forces across the lung, measurable as increased compliance. There is also reduction in gas transfer owing to loss of alveolar volume, and ultimately hypoxaemia and hypercapnia.

### Pathology

The earliest lesion is the accumulation of coal dust in macrophages at the centre of the acinus, around the respiratory bronchioles. This lesion grows to form the typical coal macule, a stellate structure often surrounded by emphysematous changes (Fig. 54.8). Macroscopically these lesions are dispersed throughout the lung and pigmented dust is seen to have accumulated in the lymph nodes also. The macules are impalpable. In addition, in more advanced simple pneumoconiosis, palpable, somewhat larger, nodules are visible that may be stellate or rounded. They are also composed of dust, disintegrating macrophages, reticulin fibres and reticuloendothelial cells but have a firm central portion of collagen. This may be irregular or, if quartz exposure has been an important factor, arranged in concentric whorls. If the miner has had heavy quartz exposure, typical silicotic lesions may be seen.

PMF is always associated with pathological evidence of simple pneumoconiosis, though the dust foci may be so sparse as to have been invisible radiologically. The lesions are black, usually irregularly shaped and limited in number. They may be sufficiently large to destroy a whole lobe or several lobes and cavitation may be present within them (Fig. 54.9). Histologically, at least two polar types may be recognized, although most examples exhibit features somewhere between the extremes [36]. The more frequent type consists of a peripheral zone of dust, macrophages and reticuloendothelial cells surrounding a relatively acellular central area consisting of collagen around the edges and amorphous, often necrotic, tissue centrally. This material is probably largely fibronectin [74,75], which has been shown to be the major protein component of PMF. Fibronectin is produced by macrophages and fibroblasts and its normal role includes binding cells together. It is a component of reticulin on light microscopy, in that it takes up silver stains and has a fibrous form. The PMF lesion typically contains elastic laminae, the ghosts of obliterated pulmonary vessels, and is usually surrounded by quite extensive emphysema.

The other type of PMF lesion appears to be the aggregation of the fibrotic nodules described above. This is often seen clearly at the periphery of the lesion, and rings or bands of dust representing the edges of earlier lesions can be seen more centrally. Studies of the dust retained in lungs of patients with PMF suggest that the former lesion tends to be associated with exposure to large amounts of high-rank coal, while the latter type is more likely to occur in miners exposed to lower-rank coal with a high quartz and silicate content [36]. However, these relationships are not clear-cut.

A third lesion occurs less frequently than the other

**Fig. 54.8** Simple coal macule showing centriacinar accumulation of dust and cells with some surrounding emphysema.

**Fig. 54.9** Section of coal-miner's lung showing progressive massive fibrosis, diffuse centriacinar emphysema and relatively sparse coal macules.

two types of PMF, although at one time it was thought possible that this might be rather more common. This is the Caplan lesion, which superficially resembles a silicotic nodule in that it shows concentric pigmented and non-pigmented layers, the dust impregnation usually being relatively light [59]. There is often little background of simple pneumoconiosis and the lesions themselves are quite rounded and well demarcated. The rings consist of collagen, which often liquefies, and the whole lesion may cavitate. The periphery usually shows features constant with rheumatoid histology, with lymphocytes, plasma cells and sometimes palisaded histiocytes. These lesions are usually multiple and rarely grow larger than 5 cm in diameter.

### Pathogenesis

The development of simple pneumoconiosis is clearly related to two factors: the total quantity of dust inhaled and its composition [43,76]. However, these do not explain all cases and individual predisposition seems important also; this is probably related more to individual efficiency of dust clearance than to immunological differences between people, studies of which have proved unrewarding [77–79]. The composition of dust is important not only in determining the pathological type of lesion but also, almost certainly, whether pneumoconiosis occurs. Given the same levels of dust, different collieries show striking differences in prevalence of pneumoconiosis, even when factors such as migration of the workforce and differing coal and ash content have been allowed for [43]. Complex

interactions occur between different minerals in coal dust that may significantly alter their toxicity; for example, quartz may be rendered almost non-toxic when mixed with certain silicates such as illite [80]. Nevertheless, the essential mechanism of simple pneumoconiosis is likely to be dust-mediated damage to macrophages, release of cytokines accompanied by recruitment of polymorphonuclear cells, resulting in activation of fibroblasts and also local initiation of emphysema by elastolysis. This latter problem is discussed in the next section.

Equally, PMF has been shown to be related to total dust exposure and to dust composition: the more dust a miner is exposed to, the greater the risk [81]. High-rank dusts are particularly liable to provoke the amorphous type of PMF, while low-rank high-quartz dusts more commonly lead to the nodular aggregating type [43]. Why a miner's disease progresses from the simple lesion to PMF is still not clear. Sometimes it is due to progressive enlargement and aggregation of quartz-induced lesions. More commonly, however, it is a diffuse fibrosing and necrotic process with marked vasculitis and considerable accumulation of dust. Its preponderance in upper lobes and, intriguingly, its predisposition to affect taller miners speak for a mechanical cause [81]. Whether this is related to local impairment of clearance, lymphatic blockage, lymph node destruction or some other factor remains to be seen, although severe destruction of hilar nodes is almost universal in miners with PMF and progressive silicosis [82,83], and it is logical to suppose that blockage of this escape route for the dust is relevant to its accumulation in the lung and provocation of a chronic progressive inflammatory reaction there. Other theories of the aetiology of PMF now seem less likely. These include autoimmune factors, which only seem relevant to the rare cases of Caplan lesions, and tuberculosis, which is no longer relevant in the UK though it was probably important in the past. Atypical mycobacterial infection has not been investigated in detail yet. It seems unlikely but cannot be dismissed as a cause in some cases.

### Coal, bronchitis and emphysema

The relationship between exposure to coal dust and chronic bronchitis and emphysema has been extremely controversial. Physicians and pathologists in mining areas have for many years believed there to be a relationship but proof has been hard to come by. In particular, in recent years the prevalence of cigarette smoking in miners has tended to hide the risks of coal dust exposure. Nevertheless, recent evidence gives strong support to the hypothesis that coal dust causes both chronic bronchitis and emphysema, adding to the effects of cigarette smoking. This evidence may be summarized as follows.

- 1 There is an increased prevalence of cough, sputum and reduction in  $FEV_1$  in miners compared with controls [45,84].

2 The risk of cough and sputum increases with increasing dust exposure in smokers and non-smokers [40,85].

3  $FEV_1$  declines in relation to a miner's dust exposure [46,47,86–89].

4 There is more emphysema in the lungs of miners who have died suddenly of cardiac disease than of non-mining controls, even when matched for smoking habit [90].

5 The risk of a miner having some emphysema in the lungs at death is proportional to dust exposure during life, if there are some pathological changes of nodular pneumoconiosis in the lungs as well [48]. This relationship holds true even when the lungs of non-smokers are examined.

6 The risk of a miner dying of chronic bronchitis and emphysema increases in proportion to dust exposure [64].

The facts make a strong case for a relationship, and would fit with the hypothesis that coal dust acts as both a cause of fibrosis and an initiator of emphysema. A common pathway, via damage to macrophages and recruitment of polymorphonuclear cells, is an attractive explanation; this hypothesis has been supported by the finding that inhalation of coal-mine dust by rats at concentrations not far removed from those to which miners have been exposed causes a neutrophil alveolitis, impaired leucocyte chemotaxis and a rise in alveolar concentrations of proteolytic enzymes [91,92]. It is particularly interesting that this response occurs within weeks of the start of exposure in view of the epidemiological finding in humans of an accelerated loss of lung function in young miners over the first year or two of exposure underground, later slowing down [93]. One might speculate that it is in this period, before the lung's defences are adapted to dealing with dust, that the process leading to emphysema may be initiated in the susceptible.

Argument has centred around the relative importance of cigarettes and coal dust in causing emphysema and airflow obstruction. In practical terms this is a red herring, in that both contribute and their effects appear to be additive and dose-related epidemiologically (Fig. 54.10). Therefore, reductions of dust levels in coal-mines will reduce the numbers of workers becoming disabled, although it will not eliminate the problem. In the past, when fewer miners smoked and dust levels were exceedingly high, it is likely that coal dust was more important overall than smoking. Currently, the reverse is almost certainly true in the West. What the future holds depends on action by both industry and society.

### Management and prevention

There is no treatment for coal-workers' pneumoconiosis and, as for all occupational diseases, the emphasis should be on prevention. This is achieved by reduction of dust levels in coal-mines by a combination of improved ventilation and use of water to suppress the dust at its source.

Fig. 54.10 Relationships between risk of acquiring a forced expiratory volume in 1 s ( $FEV_1$ ) of less than 65% of predicted and dust exposure and smoking. (Derived from data in Marine *et al.* [86].)

Special attention needs to be paid to areas where ventilation may be ineffective, such as the advancing ends of roadways. On long-wall faces, the air is driven around the face down one roadway and out the other. In room and pillar mines, curtains (brattices) are used to direct the flow of air. The effectiveness of these measures is monitored by measuring the dust concentration to which miners are exposed and in many countries this is done according to statutory obligations. In the UK, the maximum allowable concentration is  $7 \text{ mg/m}^3$ , measured as respirable dust ( $<7 \mu\text{m}$  diameter) 70 m back from the face in the return roadway, a concentration roughly equivalent to an average of  $4 \text{ mg/m}^3$  at the face. In the USA, dust is sampled within the breathing zone of face workers by personal monitors and a lower standard,  $2 \text{ mg/m}^3$ , is applied. Both these standards were based on epidemiological studies that predicted the average risk of category 2 simple pneumoconiosis after a lifetime's work at different dust concentrations (see Fig. 54.4). Tighter standards are generally applied for driving roadways where quartz levels may be high.

Whatever dust standard is applied, some miners will get pneumoconiosis because of variations in individual susceptibility. Therefore dust suppression should be accompanied by workforce radiographic monitoring. In the UK, chest radiographs are offered to all miners every 4 years and any worker showing signs of simple pneumoconiosis is offered work in less dusty conditions. This has the effect of reducing the risks of developing PMF. A further measure that may be taken is to offer miners personal protection by respirators, and this is the practice in the UK. However, this is not regarded as a substitute for good dust suppression.

These measures together have had a marked effect on the prevalence of pneumoconiosis in the UK and, with the

dwindling numbers of men employed in a contracting industry, simple pneumoconiosis and PMF are now very rare in working miners, although the latter is still seen in retired miners [55]. National statistics in other countries are harder to find, but there is no reason to suppose that similar results would not follow similar control measures.

In the UK and some other countries, an industrial injuries insurance scheme is run by the state, miners with pneumoconiosis being entitled to benefits. This is discussed in the final section of this chapter. In practical terms, the advice given to a miner who has developed pneumoconiosis depends on his age and the coal-mine in which he works. A miner developing simple pneumoconiosis under the age of 40 is very likely to develop PMF and to have his life shortened by it. Complete cessation of further dust exposure will reduce these risks. Between 40 and 55, the risks are correspondingly smaller and PMF, when it develops, may occur too late in life to cause appreciable disablement, so the management often involves offering work in conditions where the dust level is relatively low (and in the UK this offer is a statutory obligation). A man who develops simple pneumoconiosis in his last few years underground may usually be advised that the final year or two at the face will not affect his risks of PMF and premature death appreciably. These general guidelines may be modified in individual circumstances by knowledge of the dust conditions and pneumoconiosis risks in particular mines and mining areas.

**Silicosis**

**Epidemiology**

*Exposure to silica*

Silicon dioxide or silica is the most abundant compound in the earth's crust, where it is mostly found in the crystalline form known as quartz, a regular tetrahedron comprising a central atom of silicon that shares four oxygen atoms with adjacent silicon atoms. Quartz may be contaminated with other elements in trace amounts that give it colour and value as ornamental gemstones, such as agate, onyx and amethyst. Different spatial arrangements of the silicon dioxide molecule are responsible for other minerals: tridymite and cristobalite are formed by heating quartz and occur naturally in some volcanic rocks. Silica may also occur in microcrystalline and amorphous forms; the former consists of tiny crystals bonded together by amorphous silica as in flint, while the latter, probably relatively non-toxic, is not crystalline and occurs as diatomite, the petrified skeletons of minute prehistoric organisms. However, calcining (heating above 1200°C) of amorphous silica converts it into a toxic crystalline form.

Since silica occurs so abundantly, exposure to its airborne dust may occur in a very wide range of circum-

**Table 54.2** Some occupations in which exposure to quartz may take place.

stances. Some of the more important are recorded in Table 54.2. The most important numerically is cutting stone, in mining, quarrying, masonry and tunnelling. Almost all forms of mining entail a hazard of silicosis. Metal mining requires the extraction of metal-bearing ore, which is largely quartz. Even when the mineral being mined is itself a known cause of lung disease or radiological abnormalities, such as asbestos, tin or barium, the miner is usually at greater risk of silicosis. Tunnelling through granite, sandstone or other quartz-bearing rock entails an obvious hazard, although pure limestone and marble are not toxic. Stonemasonry and cleaning with abrasives are also well-known causes of silicosis. The practice of using a high-speed jet of sand for metal and stone polishing, known as sandblasting, is extremely hazardous and has been illegal in the UK since 1949. However, it continues in the USA and many other countries. Work in foundries, where molten metal is made into castings, may involve a risk of silicosis as the mould into which the metal is poured is usually made of sand bonded by resin. The sand is fused to the surface of the casting and often converted by the heat to the particularly toxic cristobalite. This is polished off the surface by a worker called a fettler, who is at potential risk of silicosis. Other foundry workers at risk are those who clean or replace the brick linings of the furnaces. These bricks (refractory bricks) are made of baked sandstone and there is also a risk of silicosis in the ceramic workers who produce them.

The production of china and earthenware involves the use of clays, usually with a low silica content, to which finely ground calcined flint may sometimes be added. The material is shaped and then fired in an oven. It is then polished, fettled and glazed, sometimes with a mixture containing powdered flint. It is clear that there are plenty of situations in this industry where silicosis may occur. Other industries with a risk of silicosis include production of silica flour, finely ground silica used as a filling in abrasives, toothpastes, polishes, paints, rubbers and plastics, production of calcined diatomaceous earths, glass-making, enamelling and production of gemstones.

### Prevalence

It is not possible to know how many workers have silicosis since notification procedures differ in different countries and many workers at risk are never surveyed by radiography. However, records in some countries, notably the UK and the Scandinavian countries, allow some overall estimates to be made. In the UK, with a working population of about 20 million, the number of workers being awarded state disablement pensions each year for silicosis fluctuates between 110 and 170. However, this figure excludes an unknown but almost certainly much larger number of workers with radiological change but no disability. The workers are predominantly from foundries, mines and quarries, refractory brick-works and potteries. A Swedish case register assessed the number of workers with radiological silicosis as having fallen from about 120 to about 70 per annum between 1950 and 1975; at the same time it was apparent that the age at which the disease was first diagnosed was progressively increasing [94]. In neither the UK nor Sweden, however, is the population at risk known.

It is likely that silicosis as it occurred in the first half of this century in mining, pottery work and sandblasting is now a very rare occurrence in developed countries. The disease prevalence has been modified in these and other industries by an increased awareness of risk and by legislative action leading to better dust suppression. For example, there has been good evidence of decreasing risk in Vermont granite workers [95], Scottish granite stonemasons [96] and diatomaceous earth workers [97,98]. On the other hand, in some industries complacency about risks has allowed poor control of exposures with consequently a relatively high incidence of preventable disease. Since the last edition of this book, the author has seen severe and

sometimes fatal silicosis in the UK among sandstone masons [99], 'limestone' crushers, barytes miners [100] and foundry workers, and this has also been reported in American sandblasters [101,102], bentonite miners [103] and silica flour workers [104], Indian slate pencil workers [105,106] and British slate-workers [107]. Finally, the expansion of mining and quarrying into economically poorer countries is likely to be attended by increasing numbers of victims of silicosis (Fig. 54.11), while the persistence of traditional stonemasonry in some such countries ensures that a steady number of people continue to get the disease from this occupation [108].

### Relationship of exposure to risk of silicosis

While it is obvious that greater risks of silicosis attend heavier exposures, the number of studies that have attempted to relate exposure to risk in numerical terms is surprisingly small. Very heavy exposures, in industries such as sandblasting, may lead to acute silicosis and moderately heavy exposures to subacute disease. Studies of classical nodular silicosis in the Vermont granite industry have suggested that the risk of clinically important silicosis was virtually eliminated by the introduction of a dust standard of approximately  $100\mu\text{g}/\text{m}^3$  [95]. More recent follow-up of this population has supported this conclusion [109]. Similar results have been obtained from a study of quartz-exposed workers in North Carolina [110], while a small but well-executed study of British gypsum workers has suggested an approximately 50% risk of developing small rounded opacities in workers exposed to  $100\mu\text{g}/\text{m}^3$  for 20 years or more [111]. An important study of Canadian gold and uranium miners has estimated the risks of radiological change in relation to careful estimates of cumulative quartz exposure [112] (Fig. 54.12).

**Fig 54.11** A typical roadside stonecrushing operation in India. Note the absence of any methods to prevent dust exposure.

**Fig 54.12** Risks of category 1 simple silicosis in Canadian hardrock miners in relation to exposure to respirable silica expressed as concentration vs. time. The different curves represent different levels of agreement between readers. (From Muir *et al.* [112] with permission.)

For category 1 pneumoconiosis to have been read by a majority of the five readers in about 3% of miners, average exposures of approximately 7 mg-year/m<sup>3</sup> are required, i.e. an exposure equivalent to 200 µg/m<sup>3</sup> for 45 years. As far as it can be interpreted, the evidence at present thus appears to show that adherence to a quartz standard of 100 µg/m<sup>3</sup> would prevent most serious silicosis but would not prevent the development of minor radiological opacities in a proportion of the workforce. The real challenge is to ensure adherence to such a standard. In the UK, the maximum allowable concentration for quartz is 0.3 mg/m<sup>3</sup>, implying a maximum cumulative exposure over a 40-year working life of 20 mg-years/m<sup>3</sup> and therefore an approximately 6% risk of radiological change in someone exposed regularly to half that concentration, using the estimates illustrated in Fig. 54.12. Rather than regular exposures to low concentrations, in real life most workers are now probably exposed to intermittent peak concentrations, sometimes well in excess of standards, and such peaks may be more relevant to the development of serious silicosis; this was almost certainly the explanation of the outbreak described in Scottish coal-miners [44].

Recent calculation of the likely exposures to quartz of two stonemasons who worked alongside each other, one of whom died from acute silicosis while the other developed PMF some years later, suggested that in the fatal case earlier prolonged exposure to low concentrations had caused fibrosis of the hilar nodes and that this was responsible for the different reactions in the two men [83]. Thus it is proposed that exposure to low concentrations over pro-

longed periods may influence the clearance of dust inhaled subsequently, and that changes for the worse in dust concentrations late in a worker's career may be particularly dangerous.

### Clinical features

It is convenient for the purposes of description to categorize silicosis as chronic, accelerated and acute, though it must be borne in mind that such subdivision is not necessarily clear-cut; these terms are used in the descriptions that follow.

### Chest radiography

The earliest sign of classical chronic silicosis is the appearance of small nodules, particularly in the mid and upper zones of the lungs. These are characteristically somewhat more dense than those in coal-workers' pneumoconiosis. They also have a tendency to increase in size gradually and are often of the r type (see Fig. 54.5) [44]. Calcification of small nodules sometimes occurs. There may be associated Kerley B lines at the bases and pleural thickening. Eggshell calcification of the hilar nodes is an almost pathognomonic feature, occurring only otherwise in sarcoidosis (Fig. 54.13).

Once silicosis has appeared on the chest film it tends to increase, both in profusion and in size of the nodules. This occurs even after exposure has ceased [94,113,114]. However, in this respect care should be taken to distinguish between true silicosis and mixed-dust pneumoconiosis, which may be seen in welders and some foundry workers for example and which runs a much more benign course, tending not to progress or evolve into PMF [114]. True silicosis frequently shows agglomeration of nodules to form the large masses of PMF [113] (Fig. 54.14). These typically have a multinodular appearance initially but later may consolidate into a contracted dense fibrotic mass, often surrounded by bullae. Cavitation may occur, and when it does evidence of mycobacterial infection should be sought. Pleural fibrosis is often extensive close to the PMF lesions.

Accelerated silicosis, associated with heavy exposures over a relatively short period of a few years, presents radiologically as progressive irregular upper zone fibrosis, sometimes with relatively sparse and indistinct nodularity [104]. The upper lobes may become replaced completely by PMF and the lower by emphysema (Fig. 54.15). Acute silicosis, which develops over months in response to exceedingly heavy exposures as in sandblasting or dry drilling [101,102,115–117], is characterized by appearances suggestive of pulmonary oedema (Fig. 54.16). Acute enlargement of the hilar nodes may occur with heavy exposure to quartz in individuals without prior exposure [83] (Fig. 54.17).

**Fig. 54.13** Chest film of hardrock miner showing eggshell calcification of hilar nodes and progressive massive fibrosis in right upper zone. The nodular, r-type lesions that formed the basis of the progressive massive fibrosis are visible, particularly in the left upper zone.

**Fig. 54.14** Silicotic lung showing grey fibrotic nodules that have coalesced in the upper and middle lobes to form massive fibrosis.

**Fig. 54.15** Chest film of patient with accelerated silicosis showing irregular upper lobe fibrosis and lower zone emphysema.

**Fig 54.16** Chest film of stonemason with 6 years of exposure to  $1 \text{ mg/m}^3$  respirable quartz following 30 years of exposure to low concentrations showing diffuse finely nodular bilateral shadowing of acute silicosis shortly before his death.

**Fig. 54.17** Chest film of 25-year-old stonemason (who worked alongside the patient shown in Fig 54.16) with 6 years of exposure to respirable quartz at  $1 \text{ mg/m}^3$  showing an acute enlargement of the hilar nodes. These later calcified and progressive massive fibrosis developed in the upper zones. The difference in the reactions to their recent very high exposures is likely to be due to prior fibrosis of hilar nodes in the patient in Fig. 54.16.

### *Symptoms and signs*

In chronic silicosis the development of small nodular opacities is not associated with symptoms or signs. However, as the disease progresses to PMF, the patient may complain of shortness of breath in proportion to the size of the lesions and the extent of emphysema. A dry cough is also often present. The condition may progress with increasing disability and ultimately cor pulmonale, although this stage is now rarely reached in chronic silicosis in most of the industries classically associated with the disease. Finger clubbing and auscultatory crackles are not a feature even of late chronic silicosis. Accelerated silicosis similarly causes no abnormal signs, but differs from chronic silicosis in that breathlessness is a relatively early feature. The very rare acute silicosis presents with rapidly increasing shortness of breath and crackles may be heard in the lungs. It progresses to death in hypoxic respiratory failure within a year or two of presentation [99].

There should not be great difficulty in making the diagnosis of chronic silicosis if an occupational history is taken. However, the radiographic appearances of accelerated disease are less familiar to physicians and chronic tuberculosis, sarcoidosis or allergic alveolitis may be considered in the differential diagnosis. However, a history of a few years of heavy dust exposure should be sufficient to prevent misdiagnosis. It is important not to be misled by a patient's understanding of the nature of the dust expo-

sure. The author has seen silicosis of severe degree in workers crushing what they believed was limestone but which clearly contained high proportions of quartz. Acute silicosis may present initially mimicking bilateral bronchopneumonia or pulmonary oedema radiographically, although the history of increasing dyspnoea over a few months together with intense exposure to stone dust should make the diagnosis easy. Again, it is important not to be deterred from the diagnosis by atypical radiographic or even pathological features and to take serious account of the occupational history [99].

### **Lung function**

Several studies have suggested that simple silicosis is not normally associated with abnormalities of lung function except in the most advanced stage (category 3) [118–121]. However, these studies have often been unable to distinguish between the effects of silicosis and possible independent effects of the dust on lung function separate from its effect in causing nodular change. Thus it may be that the functional abnormalities found are due to dust exposure, analogous to the situation in coal-miners, rather than to the development of silicosis. When abnormalities are found they are usually those of a mild mixed restrictive and obstructive pattern.

In silicotic PMF the functional changes are the same as in coal-workers' PMF, the relative amounts of obstruction and restriction depending upon the differing contribu-

tions of fibrosis and emphysema pathologically. Similar abnormalities occur in accelerated silicosis [122], while a restrictive pattern with severe hypoxaemia is to be expected in the acute disease.

### Complications

Tuberculosis and other mycobacterial infections are the most important complications of silicosis, presumably largely related to reactivation of previously quiescent lesions [94,123,124]. As tuberculous infection in childhood becomes less common so the disease in silicosis will also become rarer, although it still remains a problem in societies where tuberculosis remains endemic. As tuberculosis declines, there appears to be an increase in the incidence of infections with *Mycobacterium kansasii* and *M. avium-intracellulare*, and these organisms are recognized as important pathogens of patients with silicosis in the south-eastern USA [125]. The onset of mycobacterial infection in silicosis may be insidious, but unexpected radiological change, cavitation of PMF and the development of soft patchy opacities should alert the physician to the possibility. Fever and loss of weight, though usually only occurring with advanced tuberculosis, should not be attributed to silicosis (except of the acute type). Regular sputum examination in people with silicosis is the safest method of catching the infection early.

Other complications of silicosis include pneumothorax, associated with the combination of fibrosis and bullae [123], an increased frequency of scleroderma [126], and a tendency to renal failure due to focal damage to glomeruli and proximal tubules [127–129]. Silicotic subjects have an increased prevalence of antinuclear antibodies, and it is speculated that these, and consequent tissue damage, may be related to the damage to cells and their nuclei by quartz [130].

It is possible that workers exposed to silica have an increased risk of chronic bronchitis and airflow obstruction as a consequence of non-specific effects of dust [121,131], although recent studies of the Vermont granite worker cohort suggest that this association is not universal [132]. However, this is not as clearly established as in coal-miners, and it seems that non-smokers exposed to concentrations of quartz around 0.1 mg/m<sup>3</sup> do not run a significant additional risk of developing emphysema [133]. There have also been suggestions that quartz may be carcinogenic, especially from a Swedish study of workers in mining, quarrying, tunnelling and iron and steel trades and from studies of North Carolina dusty trades workers, of diatomaceous earth workers and of Ontario miners [94,134–136]. This controversial subject has been investigated by the International Agency for Cancer Research in a series of specially commissioned studies intended to take account of confounding factors such as exposure to other carcinogens and cigarette smoke [137]. The results

suggest that the presence of silicosis increases the risk of a worker developing lung cancer, although the evidence associating quartz exposure without silicosis and cancer is inconsistent. Recent evidence has been reviewed with the same conclusion [138]. It seems likely to the author that any carcinogenic effect is relatively weak compared to that of asbestos for example, and that control of dust exposures sufficient to prevent silicosis is likely to prevent an excess of lung cancer also. The UK Industrial Injuries Advisory Council has included lung cancer in association with silicosis in its list of prescribed diseases.

### Pathology

On macroscopic examination, the surface of silicotic lungs often shows fibrotic plaques and adhesions between visceral and parietal pleura. The lungs are pigmented and the hilar nodes are enlarged and contain fibrotic nodules that are often calcified. The cut surface of the lung is clothed with hard fibrotic nodules of varying sizes and with a characteristic whorled appearance. Emphysema is not usually as conspicuous a feature of simple silicosis as it is of coal-workers' pneumoconiosis. Where PMF has developed, it can usually be seen to have been formed by aggregation of several large simple lesions (Fig. 54.18). Cavitation of PMF may be present. Accelerated silicosis shows in addition a more irregular fibrosis in the upper zones, often with bullous emphysema in other parts of the lung. In contrast, acute silicosis looks quite different, the lungs being heavy and voluminous, without much nodular change [101].

Microscopically, the silicotic nodule arises around the respiratory bronchiole, around arterioles and in paraseptal and subpleural tissues, as well as in lymph nodes [139]. The centre of the nodule is collagen, while peripherally it shows reticulin, fibroblasts, macrophages and mononuclear cells. Dust, which may be seen to be doubly refractile using polarized light, is usually most profuse round the periphery of the nodule. However, this appearance should not be relied upon, since very fine particles of quartz may be too small to refract light and may be present in very high concentration with very little dust apparent on polarized microscopy [99]. In accelerated silicosis, in addition to nodular change, diffuse alveolar wall thickening and proliferation of type II alveolar epithelial cells may be seen [140]. In acute silicosis the alveolar walls are infiltrated by plasma cells, lymphocytes and fibroblasts, while the alveoli are filled with eosinophilic oedema fluid that is positive to periodic acid–Schiff staining [101,141]. PMF in chronic and accelerated silicosis can be seen to comprise smaller silicotic nodules at the periphery, though the centre loses this architecture and appears as a hard mass of fibrosis. Elastic ghosts of vessels may be seen within the PMF lesion and central ischaemic necrosis may occur.

**Fig. 54.18** Low-power view of silicotic nodules showing onion-skin appearance and aggregation.

### Pathogenesis

The damage caused by quartz occurs at the lung acinus and in the pulmonary, hilar and mediastinal nodes. As discussed above, physical factors determine the likelihood of dust gaining access to the acinus; once there, the particles are engulfed by macrophages. It seems likely that they are then transported to the nodes where they initiate fibrosis as discussed below. With relatively low exposures, fibrosis of nodes is the only pathological consequence; however, once fibrosis has occurred the route of egress is blocked and pulmonary fibrosis starts in the acinar regions [83]. With high initial exposures, acute enlargement of hilar nodes mimicking sarcoidosis may occur, to be followed by acinar disease once the nodes have fibrosed.

It seems likely that the crystal structure and the surface properties of quartz are important in determining its toxicity. Quartz and coesite, which have tetrahedral structures, are fibrogenic experimentally whereas stishovite, which has an octohedral structure, is not [142]. Alteration of the surface of the quartz crystal by coating it with aluminium hydroxide or iron oxide reduces its toxicity, while chemical cleaning of the surface increases toxicity [143–145]. Whether the toxic effects of quartz are due to the presence of a soluble layer of silicic acid, negative ionization of its surface, piezoelectric charging or some other factor is not clear from experimental work.

Whatever the reason for the toxicity of quartz, it seems to be mediated by macrophage phagocytosis, predominantly in the interstitial space [139,146]. Large amounts of quartz ingested by macrophages cause rupture of

phagosomal membranes, perhaps by peroxidation of lipids, escape of enzymes, and disruption and death of the cell [147]. However, smaller amounts of quartz do not necessarily cause rapid cell death, making it possible for macrophages to survive long enough to transport the dust within the lung, for example to hilar nodes, and to secrete bioactive materials. Among these may be reactive oxygen species and a wide range of cytokines [148–150]. One of these is probably interleukin 1, a substance that stimulates the proliferation of thymus-derived lymphocytes probably leading to transformation of B lymphocytes into plasma cells; this may also play some part in the propensity of patients with silicosis to produce autoantibodies.

### Management and prevention

Once a worker has silicosis there is no treatment that affects the course of the disease. Its rate of progression varies from case to case, and the prognosis is not necessarily bad. For example, a man who develops category 1 nodular change after 30 years' work in tunnelling or quarrying is unlikely to show much progression over the next 20 years, unless his disease is due to a relatively recent high exposure. Conversely, someone who develops accelerated silicosis after a year's heavy exposure is likely to deteriorate rapidly over a few more years, and patients with acute silicosis usually die within months of presentation. Attempts to find a treatment that interferes with the toxicity of silica to phagosomal membranes, although successful to some extent *in vitro*, have not produced a drug suitable for trial in humans [151,152].

The complications of silicosis should be treated according to standard therapeutic guidelines. Evidence from the 1950s and 1960s suggests that tuberculosis responded almost as well to adequate chemotherapy in silicotics as non-silicotics [123]. The newer regimens, including rifampicin, ethambutol, isoniazid and pyrazinamide, have not been tested in a controlled manner in patients with silico-tuberculosis, although they have been shown to be successful in coal-workers' pneumoconiosis complicated by tuberculosis [153,154]. Personal experience suggests that the infection can usually be cured by modern chemotherapy but that the prognosis depends on the severity of the silicosis and the extent to which this disease is accelerated by the tuberculosis. The author's practice is to treat for 12 rather than 6 months in the belief that macrophage function in such patients may be impaired. Opportunistic mycobacterial infections should be treated along the lines suggested in Chapter 20. The patient with silicosis may be eligible for disablement benefit if symptoms and pulmonary dysfunction are present and in the UK should apply to the Department of Social Security. Civil action against a negligent employer might also be justified in individuals with disability or handicapped from pursuing their trade.

Prevention of silicosis depends on preventing exposure to respirable silica dust, which presupposes that the risk has been recognized; regrettably this is not always the case. Most countries now recognize a silica dust standard aimed at preventing exposure of the workforce to more than  $100\mu\text{g}/\text{m}^3$  of respirable quartz. Whether this is adequate to prevent all cases is dubious, as discussed above, but, if enforced, at least prevents the most severe and rapidly developing cases [112,155]. Ideally, the use of quartz should be avoided if a safer substitute material is available. There is some evidence that inhalation of quartz mixed with other dusts leads to a less severe and progressive disease; this seems to be the case in coal-miners and foundrymen when the quartz levels, though above  $100\mu\text{g}/\text{m}^3$ , only represent a low percentage of the total dust inhaled. In such industries, a less tight standard, if based on appropriate epidemiological evidence, could be argued for. When high levels of quartz occur despite the best ventilation and water suppression that can be provided, respirators provide additional protection. In these high concentrations, the workers should be isolated from the environment by a complete helmet and suit with its own positive-pressure air supply [156].

Workers exposed to a risk of silicosis should be offered chest radiography at regular intervals, probably at least every 4 years, in order that the earliest signs of disease are detected and the worker protected from further exposure.

### Asbestosis

The naturally occurring fibrous minerals known as

asbestos have the common property of resistance to destruction by chemical and physical means, and have therefore acquired great usefulness to humans. There is archaeological evidence that asbestos was used in making clay pots in 2500 BC and for funeral shrouds and lamp wicks in classical times. However, widespread use of the minerals in industrial society dates back to the exploitation of the Quebec chrysotile deposits in the 1860s and the South African deposits in the 1890s. The first evidence of pulmonary fibrosis in association with asbestos use was reported at the turn of the century [157,158], and by 1930 the hazard was so well known that legislation was introduced in the UK to control the exposure of workers in asbestos factories [8]. Shortly after this, the association of asbestosis and lung cancer was reported [159], and the increased risk of this disease run by asbestos workers was confirmed epidemiologically by the 1950s [9,160]. Although it had been described as a form of lung cancer among shipyard workers in Scotland in 1947 [161], it was not until 1960 that the hitherto rare tumour, pleural mesothelioma, was shown to occur relatively frequently in South African asbestos workers [10]. Many subsequent studies have confirmed the relationship of this tumour, and of peritoneal mesothelioma, to asbestos exposure [162–165]. Thus, over the last 70 years society has been confronted with the problem of what action to take when faced with a highly dangerous but also extremely useful industrial material.

### Epidemiology

#### *Asbestos and its uses*

The minerals known as asbestos, a name derived from the Greek work for unquenchable, belong to one of two mineralogical groups, the serpentines and the amphiboles. Chrysotile, or white asbestos, is the only asbestos that is a serpentine; it is a magnesium silicate with a curly configuration and is able to shear into many smaller fibrils. All the other forms of asbestos are amphiboles, straight fibres that do not shear into shorter fibrils. They include crocidolite (blue asbestos), an iron–magnesium–sodium silicate; amosite (brown asbestos) and anthophyllite, iron–magnesium silicates; and tremolite and actinolite, calcium–iron–magnesium silicates.

Chrysotile is the most widely used form of asbestos, some 4 million tonnes being produced annually by the two major producers, Russia and Quebec Province in Canada. Amosite and crocidolite are produced mainly by South Africa, about 250 000 tonnes annually reaching the world markets. Little if any tremolite, anthophyllite or actinolite is now produced commercially, although anthophyllite has been exploited in Finland in the past. Asbestos is found naturally bound into rock and is obtained largely by underground mining. The rock is crushed and the

released fibres carded as in the wool industry; transport of asbestos from producer to user is now exclusively in impermeable plastic bags. The mineral has many uses, and its replacement by safer material has been a major problem for many industries. In particular, it imparts strength to cement, building materials and plastics, is an effective insulator and a durable friction material, is important in fireproofing and is useful as a filler in paints. It may be woven into fire-resistant materials. Thus people may be exposed to asbestos anywhere in the chain from the mine and crusher, the site of production of materials, to the place where the materials are used, deteriorate and are removed. Indeed, exposure to waste asbestos material at dumps is another area of concern. Of particular importance as situations where workers have been, and in some cases still are, exposed to asbestos are asbestos mills, thermal insulation, construction work and demolition, electrical repair work, railway engineering workshops, shipbuilding, ship repair and breaking, gas mask manufacture, boiler repair, and cement and friction product manufacture. Probably the most important occupation in developed countries is asbestos removal and abatement. Important exposures may also have been received by people living close to sources of heavy environmental asbestos pollution and by wives and families of asbestos workers as a result of their dusty clothes. There is little doubt also that careless disposal of asbestos waste has led to exposure of children playing on spoil heaps [166].

### Prevalence

It is not possible to know how many people are suffering the harmful effects of asbestos exposure. However, some idea may be obtained from statistics published by the British Government, which indicate the number of people certified by the Pneumoconiosis Boards as having asbestosis and mesothelioma and the number of death certificates mentioning these conditions [167]. Approximately 1000 people per annum die of mesothelioma in the UK and this figure is still rising (see Fig. 43.15). About 300–400 are diagnosed as having asbestosis, most being retired from work. This figure has been static for several years. While these figures largely reflect a pathogenic response to industrial conditions in the two decades after the Second World War, amphibole forms of asbestos were imported into the UK until 1980 and chrysotile imports only started to decline about that date, so that the maximum exposures in terms of numbers of people probably occurred around 1970 [168]. The incidence of asbestos-related lung cancer is not known, since it is almost never possible in individuals to be sure whether the disease was due to asbestos, cigarettes or both. However, there is no doubt that some workers develop lung cancer who would not have done so had they not been exposed regularly to asbestos; studies of

cohorts of heavily exposed asbestos workers have consistently shown lung cancer excesses as great as the numbers of mesothelioma cases. Thus in the UK although only some 50 people with asbestosis die of lung cancer each year, the numbers of patients in whom asbestos exposure may have contributed to the development of the disease may be considerably greater.

Clearly the incidence of these diseases reflects the numbers at risk of exposure and the cumulative amounts of asbestos to which they have been exposed. Incidence figures in individual countries cannot therefore be applied to other countries, where the workforce and industrial conditions may differ considerably. However, they do give some idea of the order of magnitude of the problem, for example in the UK there are 1000–2000 deaths annually from asbestos-related disease in a working population of approximately 20 million compared with about 30 000 deaths from lung cancer, largely due to cigarettes. This has been recognized as a serious public health problem, though not one that affects the general public but those members of it who work in jobs where exposure to asbestos occurs. The jobs most at risk of such exposure, as estimated from the mesothelioma statistics for England and Wales, are shown in Table 54.3.

### Relationships between exposure to asbestos and disease

There are considerable difficulties in determining the relationships between exposure and response with respect to the asbestos diseases [169]. Firstly, assessment of exposure depends on reliable measurements of airborne asbestos

**Table 54.3** Proportional mortality from mesothelioma in different jobs 1979–80. (from Peto *et al.* [168].)

	Proportional mortality ratio (all mean = 100) and numbers of deaths ( <i>n</i> )
Metal plate work (including shipyards)	700 (110)
Vehicle body builders	619 (35)
Plumbers, gas fitters	443 (201)
Carpenters	356 (254)
Electricians	291 (161)
Upholsterers	283 (19)
Construction workers	256 (187)
Boiler operators	254 (39)
Sheet metal workers	233 (48)
Production fitters	216 (304)
Engineers	211 (105)
Plasterers	203 (27)
Welders	203 (70)
Dockers	195 (69)
Builders and handymen	164 (98)
Machine tool operators	133 (179)
Painters and decorators	131 (100)

having been made for a prolonged period of the working lives of an industrial population. The measurement of asbestos is not a simple matter, depending as it does upon counting fibres of appropriate size under the microscope, and considerable variability between different counters may occur [170]. Secondly, the response is not always easily determined. With respect to mesothelioma, the response is fairly obvious but for asbestosis it may not be; for example, early radiological change or auscultatory crackles may also be subject to considerable interobserver and intraobserver error, as well as being able to be caused by other conditions. With respect to lung cancer, the confounding factor of cigarette smoking has to be taken into account.

Despite these problems, several studies have cast light on this important matter and therefore measures to prevent the diseases are somewhat more securely based now than before. A study of Quebec miners and millers has suggested that a 1% risk of significant functional or radiological abnormalities was associated with exposures estimated to be about 200 fibre-years/mL, i.e. equivalent to 4 fibres/mL for 50 years [171]. In an American asbestos cement factory, similar results were obtained [172]; in a British asbestos textiles factory it was calculated that in order to reduce the risks so that fewer than 1% of workers would develop early signs of asbestosis (defined by the authors as 'possible asbestosis', as diagnosed by the factory doctor) over a 40-year working life the fibre concentration should be between 1.1 and 0.3 fibres/mL [173]. In the UK, regulations to cover workers in jobs with recognized exposure to asbestos were introduced in 1969 and thereafter such workers were exposed to concentrations that should not have exceeded 2 fibres/mL. One study has shown a halving of the prevalence of small radiological opacities and pleural shadows in those exposed only under the regulations [174].

These results indicate that risks are different in different industries, and it seems likely that they are indeed lower in mining, milling and cement production than in textile and insulation work. However, as shown in Table 54.3, those occupations in which mesothelioma is most likely to be found are those in which the largest numbers of people are potentially exposed to asbestos; however, these are not the industries classically recognized as being at risk during production and manufacture of asbestos products but rather those in which the risks arise from secondary exposure [168]. Thus the greatest numbers of cases occur in fitters, carpenters, plumbers and machine tool operators. It seems likely that different types of asbestos have different magnitudes of effect, crocidolite being the most dangerous, followed by amosite then chrysotile. This also becomes particularly obvious when mesothelioma is considered, although in this disease measurements of exposure have rarely been available because of the long time between exposure and development of the tumour.

Studies of workers in the Quebec industry exposed only to chrysotile have shown a very low incidence of mesothelioma [175], whereas workers exposed to amosite alone and crocidolite alone seem to have suffered higher death rates from this disease, up to 4 and 16% respectively of all deaths over about 35 years [176,177]. In particular, studies of gas mask manufacturers, who used crocidolite intensively for periods of up to 5 years during the Second World War, have shown a high mortality from mesothelioma [177,178]. While this suggests that very short exposures may be risky, there is no evidence that this is so unless the exposure is likely to have been very intense. Indeed, there is evidence that risk decreases in proportion to reduction in duration of exposure [179,180]. Careful estimates of likely rates of death among a large cohort of crocidolite workers at Wittenoom, Western Australia have predicted a likely overall mortality around 14% from mesothelioma and 10% from lung cancer, together with some 7% having asbestosis at the time of death [181].

With respect to excess risk of lung cancer, a similar gradient between asbestos types seems to exist. Prolonged exposure to chrysotile seems to increase the risk by a factor of between two and three [171,182], while exposures to amosite of more than 2 years may increase it six times [176]. In crocidolite gas mask workers, exposures of several months doubled the risk of lung cancer [177], while in the Wittenoom study it was estimated that almost half of the 10% death rate from lung cancer was attributable to the asbestos exposure [181]. With respect to lung cancer it is notable that an interaction occurs between cigarettes and asbestos such that the effects of the two probably multiply the risk [183–185]. Thus if a smoker has a risk of lung cancer 10 times that of a non-smoker and someone exposed to high levels of asbestos five times the risk of someone not exposed to asbestos, then someone who both smokes and is exposed may have up to 50 times the risk of a non-exposed non-smoker.

Several studies have suggested a relationship between asbestos exposure and other malignant diseases [186,187]. Of these, the most plausible is laryngeal carcinoma, and it seems quite likely that heavily exposed asbestos workers had an increased risk of this tumour in the past [188–190]. Some have expressed scepticism about this relationship, preferring to attribute it to failure to correct for confounding effects of smoking and alcohol [191]. However, a more likely explanation is that the risks under more recent, better regulated exposures have been much reduced. It is doubtful if the early reports of excess risk of gastrointestinal cancer were valid and it may be that they represented misdiagnosis of peritoneal mesothelioma, a condition well known to be associated with heavy asbestos exposure. There is a suspicion from a case-control study that large-cell lymphoma of the oral cavity and gastrointestinal tract, a very uncommon tumour, may be associated with asbestos [192].

## Clinical features

### *Chest radiography*

The earliest sign of asbestosis is the appearance of short linear shadows about 1–3 mm thick, predominantly in the lower lung zones. These shadows, classified as category 1s or t (see Chapter 3 for details of the ILO classification), are identical to those seen in the early stages of idiopathic pulmonary fibrosis. Moreover, they cannot be distinguished from what are probably the normal appearances of the ageing lung nor from the radiological effects associated with cigarette smoking [193]. They should not therefore be regarded as in any way diagnostic of asbestosis. As the disease progresses, these shadows become more profuse and gradually obscure the vascular pattern of the lower zones (Fig. 54.19). The individual shadows also often become thicker and take on a more irregular, sometimes stellate or blotchy, appearance. Eventually the appearance of diffuse honeycombing may become apparent. Asbestosis does not occur as a result of occasional or incidental exposure. Once the lesions have appeared they usually progress, although the rate of progression may be slow and sometimes the disease, if caught early and exposure is stopped, appears to arrest [194–196]. However, it is well

recognized that the first signs of asbestosis may occur after asbestos exposure has ceased [197,198]; in these circumstances, progression tends to be comparatively slow. When the radiological appearances of asbestosis appear for the first time after exposure to asbestos has ceased, there is almost always a prolonged history of exposure to the material, usually at relatively low concentrations.

The radiological effects of ageing and cigarette smoke do not usually extend beyond category 1 on the ILO scale of profusion, so that irregular shadows more profuse than this can be taken to indicate pulmonary fibrosis. Whether this fibrosis is due to asbestosis depends on the history of exposure, although radiological evidence may also be helpful in that the presence of pleural plaques, obliteration of costophrenic angles or diffuse pleural fibrosis is indicative of asbestos exposure. Calcified pleural plaques are indeed diagnostic of this, and if they are associated with interstitial fibrosis it is usually difficult to deny that any associated lung fibrosis is due to asbestosis. These pleural lesions are described in Chapter 43.

High-resolution CT is more sensitive than standard chest films for the detection of early interstitial fibrosis in workers exposed to asbestos and nicely demonstrates the peripheral and basal accentuation of the fibrosis. CT also shows calcified and non-calcified pleural disease and the presence of these features helps to tip the diagnostic scales in favour of an asbestos aetiology for the fibrosis in cases of clinical doubt. However, the absence of plaques on CT

**Fig. 54.19** Lower part of chest film of a patient with asbestosis showing well-marked irregular fibrosis and honeycombing.

should not be taken to exclude the presence of asbestosis if there is an adequate history of exposure, since not all plaques are visible on the scan. In the author's opinion, in the absence of pleural disease it is not possible to differentiate between early asbestosis and early cryptogenic fibrosis from the CT features alone; equally pathologists are reluctant to diagnose the cause of fibrosis from macroscopic inspection of the lung! However, a few features help to increase the confidence with which a diagnosis of asbestosis can be made [199]. Pleural fibrosis with bands extending into peripheral lung are common in asbestosis (Fig. 54.20) and rare in the cryptogenic disease, while fibrosis extending into upper lobes is uncommon in asbestosis. It should be noted that reports showing clear differences between these two diseases are at serious risk of bias from selection of the relatively few 'typical' subjects studied.

### *Symptoms and signs*

The patient always gives a history of working either directly with asbestos or adjacent to others working with the material, usually in very dusty conditions and over a prolonged period. It is most unusual nowadays in the West to see the disease in anyone who has been exposed to asbestos for less than 20 years. As mentioned above, the condition may present after exposure has ceased. The symptoms are exertional dyspnoea and, often, dry cough. The dyspnoea gradually becomes more severe and eventually may be completely disabling, the patient dying of cardiorespiratory failure. This course is uncommon, most patients developing the disease relatively late in life and their disability being moderate rather than severe. The

most common presentation in the western world is a patient who has been found to have minor radiological changes (usually pleural) on a coincidental chest radiograph, has no symptoms, but has crackles audible at the bases and minimal interstitial fibrosis on CT. However death from one of the malignant complications of asbestos exposure, bronchial carcinoma or mesothelioma, is of much more frequent occurrence. Although dependent to some extent on individual susceptibility, prognosis is also related to the amount of asbestos to which the worker has been exposed; thus heavy exposures resulting in early development of disease may be expected to result in more rapid progression, whereas asbestosis developing only after 30 years of work with the material may be expected to progress very slowly and does not usually itself influence life expectancy.

The earliest sign of asbestosis is the presence of repetitive end-inspiratory crackles, heard at the lung bases posteriorly or in the axillae [200,201]. These signs are not specific to asbestosis but in the presence of a convincing history of exposure are strong evidence of the disease. As the disease progresses, the crackles become more profuse and are heard earlier in inspiration, in early expiration and further up the lung. Only at this relatively late stage in the natural history of the disease is clubbing of the digits usually present [202]. As the disease reaches its terminal stage, diminished chest wall movements, tachypnoea and evidence of cor pulmonale may be detected, with cyanosis, tall jugular *a* waves, right ventricular heave and gallop rhythm. Gross oedematous right heart failure is uncommon, the patient usually dying of hypoxic respiratory failure.

**Fig. 54.20** High-resolution CT of patient with pleural fibrosis showing early interstitial fibrosis and marked pleural thickening with calcification and bands passing into the peripheral lung.

### Lung function

The functional abnormalities associated with asbestosis are progressive reduction in carbon monoxide diffusing capacity, vital capacity and total lung capacity, with normal residual volume [203–205]. Compliance is decreased and lung recoil pressure increased. Hyperventilation and arterial oxygen desaturation may occur on exercise in the more advanced stages. These changes are not of course diagnostic of asbestosis but characteristic of any form of chronic pulmonary fibrosis.

Some authors, taking cognizance of the fact that the earliest pathological change involves respiratory bronchioles, have shown early changes in expiratory flow rates in subjects with relatively short but heavy exposures [206,207]. From a practical clinical point of view the most useful test for detection of significant asbestosis is the *DLCO*, and deterioration in this closely mirrors disease progression. Only as the disease reaches an advanced, and usually clinically very obvious, stage do lung volumes deviate sufficiently from the predicted range to be unequivocally abnormal. In keeping with this, the transfer coefficient (*Kco*) is usually low. However, this index of lung function may be paradoxically increased in patients with extensive pleural fibrosis [208], so the combination of pleural and pulmonary fibrosis in an asbestos worker may be associated with low *DLCO* and alveolar volume and a relatively normal *Kco*.

### Pathology

The macroscopic appearances of asbestosis are of grey-white fibrosis, most marked in the lower zones. If the disease is advanced, honeycomb changes may be apparent (Fig. 54.21). Parietal pleural plaques are usually

present and diffuse fibrosis involving both layers of pleura and extending into the surface of the lung may also be seen. These pleural changes are described in Chapter 43.

Microscopically, the earliest change is an alveolitis around asbestos fibres in the respiratory bronchioles [209–211]. In experimental lesions the first response to asbestos deposition in the acinus can be seen to be an influx of macrophages, some of which disintegrate and become surrounded by fibrin and subsequently collagen [212]. The most peripheral airspaces and the interstitium are initially free of fibrosis but as the lesion develops it can be seen to spread into alveolar walls and along the respiratory bronchioles to the distal alveoli, resulting in widespread diffuse fibrosis (Fig. 54.22). The appearances of honeycombing result from a dilatation of small bronchi and bronchioles in uninvolved parts of the lung due to their retraction by surrounding fibrosis [213]. Massive areas of fibrosis have been described but are different from PMF in other pneumoconioses in that they represent confluent areas of irregular fibrosis. Caplan lesions have also been described very rarely [214].

Asbestosis may be complicated by silicosis in asbestos miners, as has been described in South Africa; when this occurs the distribution of the diffuse fibrosis may be predominantly in the upper zones of the lung. There is not thought to be an increased frequency of tuberculosis in patients with asbestosis, although workers with concomitant silicosis may develop this complication, especially if, as in South Africa, the disease is endemic in the area. As mentioned previously, the most important complication of asbestosis is bronchial carcinoma.

The feature that differentiates asbestosis from other forms of pulmonary fibrosis is the presence of asbestos in the lungs. On light microscopy, asbestos fibres are generally too fine to be seen and the clue comes from the

**Fig. 54.21** Lung slice showing lower zone fibrosis of asbestosis. Two areas of relatively normal lung, to left and right, are separated by coarse irregular fibrosis.

**Fig. 54.22** Low-power view of early asbestosis showing peribronchiolar fibrosis.

**Fig. 54.23** Asbestos bodies in human lung. A few small uncoated fibres are also visible.

presence of ferruginous bodies. These are yellow-brown structures, about 2–5  $\mu\text{m}$  in width and up to 150  $\mu\text{m}$  in length. They have a beaded appearance and clubbed ends (Fig. 54.23) and probably derive from deposition of ferritin and protein onto the asbestos fibre within the body of macrophages. Electron microscopy shows the asbestos body to be formed around a single fibre of asbestos, usually an amphibole, though it may occasionally form around other fibrous particles [215–217]. Such structures also form around other mineral fibres, most of which do not have the same pathogenic significance of asbestos, so

care should be taken before concluding that they are indeed due to asbestos exposure. Electron microscopy with energy-dispersive X-ray spectroscopic analysis is the only sure means of identifying the minerals present in the tissue [218]. This expensive technique is not necessary for clinical purposes but is useful in research on mineral-induced lung disease and is increasingly being used in civil litigation in efforts to strengthen evidence of exposure to asbestos.

Often relatively few asbestos bodies may be seen, even in advanced asbestosis. This is because only a very small

proportion of inhaled asbestos fibres are dealt with in this way by the lung's defences. Most fibres remain uncoated but are often less than  $0.5\mu\text{m}$  in diameter and therefore invisible on light microscopy. Special techniques of lung ashing and examination of residues by phase-contrast optical microscopy or electron microscopy allow an assessment to be made of the numbers of fibres that may be present in the lung. Using optical microscopy, such studies have shown up to 30 000 fibres/g of dried lung in apparently unexposed individuals, counts of 100 000 fibres/g or more in asbestos workers and over 3 million fibres/g in subjects with asbestosis [219,220]. Use of electron microscopy allows these figures to be multiplied by one or two orders of magnitude but also shows that many of the fibres in unexposed people are minerals other than asbestos [221].

### Pathogenesis

In order for asbestosis to develop, sufficient numbers of fibres must penetrate to the acinar parts of the lung. The aerodynamic characteristics of fibres are such that their diameter must be less than about  $3\mu\text{m}$  in order for them to remain suspended in the inspired air to acinar level. Fibres are arbitrarily defined as structures three times as long as they are wide; thus a fibre may be of almost any length if sufficiently narrow and indeed many crocidolite fibres are only  $0.1\mu\text{m}$  in diameter. However, there is increasing evidence that in order to have a pathogenic effect fibres must be too long to be engulfed completely by macrophages and therefore fibres of less than  $10\mu\text{m}$  are probably of little

pathological significance [139,222] (Fig. 54.24). Furthermore, the shape of the fibre is probably important, such that chrysotile, with its curly configuration, is more liable to be intercepted by contact with bronchial walls than are the straight amphibole fibres [223]. Once the fibre has penetrated to acinar level, another factor of pathogenic importance is its durability [224]. This may prove to be of overriding importance in assessing the possible health effects of new fibrous substitutes for asbestos, such as glass and other synthetic fibres. A fibre that remains intact despite the attack of the lung's macrophages and the physical and chemical trauma of residence within a constantly moving organ is the one with the greatest potential harmfulness.

The mechanisms of fibrogenesis are not fully understood. *In vitro* studies show asbestos not to be very toxic to macrophages, though some studies have indicated that release of cytokines and reactive oxygen species may play a part [139]. Lavage studies in rats have shown only a moderate immediate cellular response to asbestos inhalation, in contrast to the rapid recruitment of polymorphonuclear cells that occurs with coal and quartz inhalation [225]. Nevertheless, like the human lung, the rat lung responds by production of diffuse fibrosis and bronchial carcinomas. Even more strikingly, as discussed in Chapter 43, injection of asbestos of any type into the pleura or peritoneum of a rat produces a dose-dependent incidence of mesothelioma; with appropriate doses almost 100% of rats die of this disease [226].

The epidemiological differences between the effects of chrysotile and of the amphiboles (i.e. the former seems to

Fig. 54.24 Macrophages in culture with asbestos: several have engulfed short fibres but in two cases the fibres are too long and protrude through the cell membrane.

cause less disease dose for dose than the latter) may be explicable on the basis of two factors: (i) chrysotile is filtered out more efficiently by the airways because of its shape and its tendency to clump into groups of fibres and (ii) once inhaled, chrysotile is gradually broken up into tiny fibrils that because of their size are gradually removed by macrophages. This hypothesis explains why mesothelioma is so much less common in workers exposed to chrysotile than in those exposed to amphiboles, since in the long time period required for sufficient asbestos to migrate to the pleura chrysotile is broken up. However, it still has time to initiate the processes of fibrogenesis and bronchial carcinogenesis. In support of this hypothesis, studies of the lungs of workers exposed to a mixture of asbestos types have in general shown unexpectedly high proportions of amphiboles in relation to the amounts to which they were exposed during life [224,227].

### Management

People exposed to asbestos may present to their doctors for a number of different reasons, and it is more usual to see such individuals before they develop disease than after. The usual reasons for presentation are discussed below.

1 A well person with no radiological abnormality has found that he or she has been or is currently exposed to asbestos. This is often due to the discovery of fixed asbestos materials in the house or workplace rather than to actual work with the material. Such people should be reassured that the risks of such incidental exposure are of no account. However, the physician should give general advice on future avoidance of exposure to airborne asbestos. If the workplace is the suspected source of exposure, the employer should be encouraged to seek the opinion of an occupational hygienist, and if thought necessary the regulatory authority, in the UK the Health and Safety Executive, should be contacted.

2 A fit person has been found to have pleural plaques on chest radiography. Again, the individual should be reassured once it has been established that current exposure to asbestos has ceased. Advice against smoking should be given but follow-up in clinics should not be arranged, since it serves no purpose other than to increase the subject's anxiety. There is no evidence that pleural plaques increase risks of any other disease, and any risks of lung cancer and mesothelioma relate to the history of asbestos exposure and, in the case of lung cancer, to smoking.

3 An asbestos worker presents with early irregular basal X-ray shadows and no symptoms. The diagnosis is made on the occupational history, radiological findings and presence of repetitive inspiratory crackles. Further exposure to asbestos should be discouraged, since detection at

an early stage may be associated with only very slow progression unless more asbestos is added to the load in the lungs. In the UK, if the worker has been employed, as opposed to self-employed, he or she should be encouraged to apply for pneumoconiosis benefit, which is awarded in proportion to the disability as assessed by the doctors of the Medical Board for Respiratory Diseases of the Department of Social Security. Since the risk of lung cancer is much increased, the individual should be discouraged from smoking. Such patients commonly sue their previous employers.

4 Patients presenting with late-stage, previously undiagnosed, asbestosis should be encouraged to apply for pneumoconiosis benefit. Treatment should be along routine lines for patients with respiratory failure, with provision of domestic aids, oxygen for symptomatic relief of breathlessness, diuretics for right heart failure and antibiotics for acute infections. Corticosteroids are of no value and should be avoided. In a patient of appropriate age and general health who does not smoke, transplantation would be an option (see Chapter 59).

### Prevention

In taking steps to prevent asbestos-related diseases, two important points need to be borne in mind. Firstly, mesothelioma is almost always due to exposure to amphiboles and therefore avoidance of all use of these types of asbestos will eventually largely eliminate the disease. In the UK, crocidolite has effectively been excluded (by the imposition of very strict hygiene standards) since 1970 and amosite use has been restricted in the same way since 1980. Furthermore, tight regulation of asbestos removal since 1970, especially where amphiboles are concerned, should have ensured that mesothelioma would soon become a rare condition once again. However, it has now become apparent that most cases of mesothelioma occur in people working in effectively unregulated industries, with exposure to asbestos that has been *in situ* for many years, and that the epidemic of this disease is therefore likely to peak around the year 2020 and only decline to current levels some decade or two after that [168]. Secondly, asbestosis and lung cancer develop in relation to the dose of asbestos to which people are exposed. Therefore, occasional and incidental domestic or workplace exposures are likely to be of no significance. Such risks of death have been calculated to be considerably less than those associated with driving daily to work or living in a house with a smoker for example [169]. However, the risks that are run by someone working with asbestos on a regular basis are more easily imagined. While it is probable that risks of clinically significant asbestosis may be eliminated by preventing workplace exposure to more than 0.5 fibres/mL over a lifetime, these exposure levels may still entail a risk of developing lung

cancer, dependent partly on the smoking habits of the workforce, rising to perhaps 6 per 1000 for men exposed to the mineral for 35 years from the age of 20. For a discussion of these risks and the assumptions made in calculating them, the reader is referred to the monograph of Doll and Peto [169].

Thus the prevention of asbestos-related disease depends on reduction or elimination of exposure to the mineral. This should be achieved by the enforcement of a strict code of practice in handling the material, by increased public awareness of its hazards (thus ensuring it is handled with respect) and by the setting of appropriate hygiene standards. Currently in the UK the maximum allowable concentration of chrysotile is 0.5 fibres/mL, while the use of crocidolite and amosite is effectively prevented by a standard of 0.2 fibres/mL. Regulations also enforce the wearing of protective clothing and full-face respirators by workers removing asbestos, effective sealing off and vacuuming of such areas and safe disposal of the waste material. Other countries have their own regulations, which range from a complete ban on the use of asbestos to none at all.

### **Disease due to other silicate materials**

Although coal, quartz and asbestos are the three minerals containing silicon to which humans are most frequently exposed, there are other compound silicates that either occur naturally or are synthetic which may expose the lungs to hazard. In general, their toxic effects are likely to be similar to those of coal if they produce amorphous airborne dusts or similar to those of asbestos if they produce fibrous dusts. The most important such minerals are kaolin, fuller's earth, mica and cement, which are all amorphous; talc, which has a plate-like shape; and mullite, erionite, attapulgite, sepiolite and wollastonite, which are fibrous. Synthetic fibres are also considered here, as is oil-shale, which contains a complex mixture of clay minerals.

### **Non-fibrous silicates**

#### ***Talc***

Talc is a hydrated magnesium silicate with multiple uses as a lubricant and filler in cosmetics, paper and rubber manufacture, paints and building materials. It is mined in Canada, the USA, Russia, Italy and the Pyrenees, and in some of these places is associated geologically with tremolite asbestos. Cosmetic talc should be free of asbestos [228,229], but industrial grades may contain it as well as other minerals such as quartz and accordingly should be carefully handled.

The coincidence of talc and fibrous tremolite in the mineral deposits has caused some difficulty in deciding

what the true effects of talc are on the lung. Talc miners have been shown to have an increased risk of pleural plaques, diffuse pulmonary fibrosis and lung cancer [230–232]. However, these effects were probably due to the tremolite (though this is of little consequence when it comes to protecting the miners and millers, who continue to be exposed to both minerals). In places where exposure has been to pure talc, the disease described is a nodular pneumoconiosis with a tendency for the small nodules to aggregate and form PMF, similar to silicosis [232]. There is no evidence that exposure to talc is carcinogenic unless associated with fibrous tremolite. A follow-up survey of people who had previously been treated for pneumothorax with insufflation of medicinal grade talc into the pleural space showed no excess mortality and no cases of mesothelioma [233].

Some rather more bizarre hazards of talc have been described. One man has been recorded as giving himself pneumoconiosis by obsessive overuse of talcum powder [234], another by enthusiastic work as a talc aerosol inspector [235] and a third by inhaling (illegally) the contents of medicinal capsules prior to performing as a punk-rock drummer [236]. Talc may also initiate bronchoconstrictive episodes when inhaled by babies [237] and is of course one of the means by which intravenous drug abusers accidentally kill themselves [238].

#### ***Kaolin and other clays***

Kaolin consists mainly of the mineral kaolinite, a hydrated aluminium silicate, and is produced in south-west England, the USA, Japan, Egypt, Czechoslovakia and Germany. It is quarried by washing it out of the deposits with water and is then dried and milled for use in ceramics, paints, paper, soap and pharmaceuticals. Both simple and complicated pneumoconiosis have been described in workers in the milling and bagging plants, the pathological and radiological appearances being very similar to those of coal-workers' pneumoconiosis [239,240]. In particular, kaolin does not produce the highly collagenous lesions seen with quartz inhalation, unless the worker has been exposed to a mixed silica-containing dust. Studies of lung function in patients with kaolin pneumoconiosis have shown results similar to those described in coal-workers, with impairment associated with PMF and a possible dust-related obstructive and restrictive component in subjects with simple pneumoconiosis [241–243].

Fuller's earth is an absorbent clay that was named after its early use in fulling, the removal of grease from wool. It usually contains calcium montmorillonite, an aluminium silicate, and is obtained by quarrying in the UK, the USA and Germany. It is used as a filter, filler and binder for foundry moulds. A relatively benign simple pneumoconiosis, occasionally progressing to PMF and very similar

to kaolin pneumoconiosis, has been described in production workers [244,245].

Oil-shale was mined in Scotland until 1962 for the production of mineral oil. Other deposits have been mined in France and Estonia, while enormous amounts wait to be exploited in the Rocky Mountains in the USA. The rock is crushed and heated in retorts to produce the oil which is then refined. Skin cancer is a well-known hazard of workers exposed to the oil [246], although pneumoconiosis has been described in the miners and dust-exposed surface workers [247,248]. The disease appears relatively benign, although PMF has occurred occasionally and a mixed restrictive and obstructive dysfunction has been described in the simple disease [249]. It is probably due largely to the kaolin component of the shale. Epidemiological studies have shown no associated lung cancer hazard [250].

It should be remembered that mining or quarrying and production of clays may expose workers to a risk of silicosis if the clay deposit contains substantial amounts of quartz. This may be the case with ball clays, used in earthenware and bricks, and bentonite, which is used in the same applications as fuller's earth [103,251,252]. In addition, some clay minerals such as palygorskite, attapulgite and sepiolite have a fibrous habit and are mentioned below.

### *Mica*

There are two commercially important forms of mica: muscovite, a potassium–aluminium silicate, and phlogopite, a magnesium–aluminium silicate. The former is transparent and both are resistant to heat and electricity. They are mined in North America and India and used in furnace windows, as fillers in papers and paints, and in insulating materials in the electricity industry. There have been occasional reports of pneumoconiosis among workers exposed to ground mica, usually of a nodular type but diffuse interstitial fibrosis has been described [253–256]. However, such episodes seem to be rare.

Vermiculite is another form of mica mined mainly in the USA and South Africa and used predominantly as an insulation material. Some of the mineral deposits are contaminated with fibrous amphiboles and it is likely that the reports of radiological disease and increased cancer mortality in these workers have been largely due to this contamination [257–259].

### *Cement*

Cement is produced by heating a crushed mixture of limestone and clay or shale in a long rotary kiln. The clinker produced is mixed with gypsum and slag, crushed, and ground in ball mills. The product consists largely of

calcium silicates and aluminates. There is some evidence that cement workers may develop simple pneumoconiosis and decrement in ventilatory capacity, although adequate studies need to be carried out [260,261]. Workers handling and producing asbestos cement are at risk from exposure to the asbestos.

### **Fibrous silicates**

Enough is now known about the nature of tissue damage from fibrous minerals to be able to generalize about risks to health from exploitation of any such new material. It is stressed that this is a generalization and that there may be exceptions; nevertheless, this information may be used as a guide to manufacturers and as a means of designing preventive measures in industry [262]. The factors that determine toxicity, in terms of both fibrogenicity and pleural carcinogenicity, are the length and diameter of the fibres to which workers are likely to be exposed and the solubility of the fibres. Fibres longer than about 10 µm are likely to be retained in the lung, while shorter fibres are likely to be removed. Thus short fibres act like amorphous dusts and are generally harmless unless inhaled in very high concentrations. Fibres wider than 3 µm are unable to reach the respiratory epithelium in sufficient numbers, and can also therefore be regarded as relatively benign. Once in the acinus, the factor that primarily determines toxicity is the solubility of the fibre and therefore its ability to remain in the tissue [263,264]. Relatively soluble fibres such as most glass fibres will dissolve quickly and cause no disease whereas insoluble fibres such as some ceramic and carbon fibres might be expected to persist much longer and ultimately lead to fibrosis and sometimes neoplasia.

### *Erionite*

Erionite is a naturally occurring fibrous aluminium silicate found in volcanic rocks. It is not used commercially but may be the cause of disease in people who are digging through the rock. In particular, it occurs in parts of Turkey where villagers have been in the habit of cutting into the rock to make their homes and to produce building materials and stucco [265–267]. The inhabitants of these villages have been shown to have a very high rate of pleural plaques, pulmonary fibrosis, lung cancer and mesothelioma. In other words, the mineral behaves in the body like asbestos, which it resembles physically but not mineralogically. These observations have been important in supporting the hypothesis that the effects of asbestos are due to its size and shape rather than its chemical and mineralogical characteristics. They imply therefore that other minerals of similar shape and size may have similar effects and should therefore be handled with care.

Deposits of erionite occur in other parts of the world, particularly in desert areas of Nevada and Utah in the USA. There is a potential for human exposure, for example in digging missile silos, and one patient who lived and worked in such an area has been described as having pulmonary and pleural fibrosis associated with erionite in his lung [268].

### *Synthetic fibres*

The realization that the fibrous shape of asbestos is likely to be important in the pathogenesis of disease has led to anxiety about the production and use of synthetic glass wool, rock wool, carbon and ceramic fibres, which are widely used as asbestos substitutes. Experimentally, some of these fibres have been shown to cause mesothelioma if they are introduced into the rat pleura and are sufficiently fine and long [269,270]. Studies of human workforces exposed to them have not so far shown any significant degree of hazard from mesothelioma or non-malignant respiratory disease, although there is some evidence from very large epidemiological studies in Europe and the USA of a slight increase in risk of lung cancer in workers with prolonged exposure to rock/slag wool [271,272]. Some of this risk may have been a consequence of exposure to other carcinogens in the early stages of the industry, but an open mind should be kept, especially with respect to the use of relatively insoluble fibres. Moreover, the apparently low incidence of disease may be due to the relatively low exposure of workers to fine respirable fibres and should not be taken as an indication of harmlessness if finer fibres are to be used in future applications.

### *Other fibrous silicates*

Mullite, another aluminium silicate, occurs as a result of combustion of coal and is a component of fly ash, the ash residue from power stations. It has a fibrous shape, though the fibres tend to be short. It is commonly identified in human lungs when their mineral content is being measured by electron microscopy, although whether it is harmful has not been established. Interstitial lung disease has been described in men using it in the production of cat litter [273]. Attapulgite, palygorskite and sepiolite are fibrous clay minerals that have commercial applications as absorbents and filter materials. Again, there have been occasional reports of pulmonary fibrosis in those working with attapulgite and it seems possible that there may be a hazard with high exposures [274]. There is also a suspicion that attapulgite miners may have an excess risk of lung cancer, though this cannot be said to be firmly established [275]. In general the fibres are rather short and therefore likely to be less harmful than asbestos. Wollastonite, a fibrous calcium silicate, is used in ceramics and as an asbestos substitute. These fibres are also short but there

has been one report of possible pulmonary fibrosis and pleural plaques in exposed workers [276].

## **Siderosis and mixed-dust pneumoconioses**

### **Siderosis**

Pure siderosis is due to deposition of iron oxides in the lung, where they are taken up by macrophages in both the alveoli and interstitial tissue. No fibrous reaction occurs but the chest radiograph shows multiple radiodense nodules due to the presence of the iron (Fig. 54.25). The condition occurs in arc welders and oxyacetylene cutters due to the presence of iron oxides in the fume from the heated metal [277]; it should be noted that welders and cutters may also be exposed to other metals and carbon in the fume and that pneumoconiosis in such workers cannot always be assumed to be pure siderosis. Siderosis also occurs in silver polishers, who use iron oxide (jeweller's rouge) to polish the metal [278]. The radiological changes of siderosis tend to regress after exposure ceases and the condition in its pure form is not associated with abnormality of lung function [279]. There has been debate about the possible carcinogenicity of inhaled iron, based on the known increased hazard in haematite miners (see next section) and an excessive death rate from lung cancer noted by the British Registrar General. However, it seems likely that iron itself is not carcinogenic and that when cancer occurs it is probably due to concomitant exposure to other carcinogens in either cigarettes or the occupational environment.

### **Mixed-dust pneumoconioses**

Mixed-dust pneumoconiosis is a convenient term covering pneumoconioses occurring in a variety of trades in which the inhaled dust is a mixture of silica and other substances. Strictly speaking, coal-workers' and shale-miners' pneumoconioses are mixed-dust pneumoconioses. The pathological reaction and its physiological consequences depend on the constituents of the dust though, in general, the higher the proportion of silica, the more closely the disease resembles silicosis. Haematite miners' lung is an example of this. The iron ore, haematite, was mined in Cumbria where it was noted that miners developed pneumoconiosis often after many years of exposure underground [280,281]. Both simple pneumoconiosis and PMF occurred and at postmortem the lungs were noted to be brick-red in colour [282]. Pathologically, the appearances are those of silicosis with the additional feature of accumulation of iron pigmentation. Haematite miners in the UK were shown to have an increased risk of lung cancer, although this was almost certainly related to exposure to radon daughters in the mine atmosphere [283].

**Fig 54.25** Welders' siderosis showing diffuse pin-point opacities. The peripheral lesion in the right mid zone was removed at thoracotomy and proved to be a carcinoma.

Other workers who may develop pneumoconiosis related to inhalation of a mixture of iron oxides and silica are foundry workers, especially fettlers, welders and burners, boiler scalers and ochre miners. Any worker exposed to a mixed dust containing more than about 10% quartz is liable to develop silicosis.

### **Berylliosis**

Beryllium ore (beryl or beryllium aluminium silicate) is mined predominantly in South America. The metal is extracted from the crushed ore by heating and treatment with sulphuric acid or fluoride and is used as an alloy in the manufacture of components in X-ray equipment, atomic reactors, the aerospace industry, armaments and heat-resistant ceramics. These alloys have the properties of tensile strength, resistance to corrosion, metal fatigue and heat, as well as being non-magnetic, transparent to X-rays and of high electrical conductivity.

### **Effects of exposure to beryllium**

Exposure to beryllium fume or salts may occur in extraction, refining or production of alloys. In the UK a few cases of berylliosis have occurred in workers producing and breaking fluorescent lights, which used to be coated with the metal, and in refinery workers [284]. The greatest

experience of the harmful effects of beryllium comes from the USA, where a registry of cases has been kept at the Massachusetts General Hospital since 1952 following a postwar epidemic of the disease [285–287].

Exposure to high concentrations of beryllium fume may cause an acute toxic pneumonitis, with oedema of mucous membranes from pharynx to small airways together with pulmonary oedema [285]. The radiograph shows evidence of the pulmonary oedema and the clinical signs are tachypnoea, cyanosis and diffuse inspiratory crackles. Mild cases of the condition are usually self-limiting but severe cases may need treatment with oxygen and corticosteroids to prevent a fatal outcome. Approximately 10% of patients with acute berylliosis have progressed to the chronic form of the disease.

Chronic berylliosis was first described in 1946 [286]. It is different from other mineral pneumoconioses in that it is a systemic hypersensitivity disease, with principal effects on the lung and skin. Sensitization usually occurs by inhalation of dust or fume of the metal or its salts but may occur by introduction of beryllium into the skin through an abrasion. Only a small proportion of those exposed have developed the disease, often after a prolonged latent period and sometimes after a relatively light exposure. Cases have occurred in wives of workers, presumably from beryllium carried on clothing, and in people living close to beryllium refineries.

### Clinical features

The disease may present years after exposure to beryllium has ceased [288,289]. It should be a routine in patients presenting with apparent sarcoidosis to ask about possible exposure to the metal in the past, as in ceramics, metal alloying, the nuclear industry or even dental prosthetics [290]. It has also been described in wives of such workers who have been exposed to their husbands' contaminated clothes [291]. The symptoms are cough and dyspnoea and the course of the untreated disease is usually progressive. However, an apparently self-limiting variant has been described in people exposed to beryllium in rather low concentrations [292], in whom minor radiological changes appeared and subsequently disappeared without treatment. Finger clubbing only occurs rarely and inspiratory crackles are not a feature of the early disease, although they may appear as fibrosis becomes established. Hepatosplenomegaly may occur, as may macular skin lesions, although generalized lymphadenopathy and uveitis are not features. Pneumothorax and cor pulmonale are complications of advanced disease. As in sarcoidosis, hypercalcaemia, hypercalciuria and nephrocalcinosis may also occur, but the other less common manifestations of sarcoidosis such as cardiac and neurological involvement have not been described.

The radiographic changes are initially a diffuse fine granularity that evolves into a reticulonodular pattern and finally irregular fibrosis, often of a coarse generalized type as in chronic sarcoidosis [293] (Fig. 54.26). Bilateral hilar adenopathy may occur but only when there is also evidence of interstitial lung infiltration. As would be expected, the functional changes are those associated with

diffuse interstitial disease, with reduced *DLCO* and progressive reduction in lung volumes and compliance as fibrosis increases [294].

### Pathology

The gross appearances of chronic berylliosis at an advanced stage are of irregular fibrosis with bullae and cyst formation. The important microscopic feature is the non-caseating granuloma. At an early stage, discrete follicles of epithelioid cells surrounded by lymphocytes and plasma cells are seen in the interstitial tissues and alveolar walls. Similar appearances are found in lymph nodes, skin lesions, liver and spleen. Langhans' giant cells develop by fusion of the epithelioid cells, and sarcoid-type inclusion bodies may be seen. These pathological features are indistinguishable from those of sarcoidosis (Fig. 54.27). As the disease progresses, interstitial pulmonary fibrosis occurs, which may proceed to widespread acinar destruction and dilatation of small airways, to produce honeycombing.

### Pathogenesis

The characteristic immunological features of beryllium disease are cutaneous anergy to tuberculin, delayed skin reactivity to beryllium, and *in vitro* stimulation of lymphocytes by beryllium salts so that they transform into lymphoblasts and produce lymphokines such as a factor that inhibits macrophage migration [295]. In addition, the pathological features of mononuclear cells and giant cells lend weight to the concept that berylliosis is due to a delayed hypersensitivity reaction to the metal and its salts.

**Fig. 54.26** Chronic berylliosis in ex-beryllium refiner showing diffuse irregular pulmonary fibrosis.

**Fig. 54.27** Sarcoid-like granuloma in the lung of patient with berylliosis.

Bronchoalveolar lavage studies in patients with chronic berylliosis have shown increased cell numbers, almost 80% being lymphocytes, most of the T subtype [296]. These cells have been shown to react to beryllium more rapidly than blood lymphocytes, suggesting that a high proportion are sensitized to the metal.

It seems likely therefore that certain individuals react to inhaled or absorbed beryllium, coupled to protein as a hapten, via a cellular immune response. Perhaps ingestion of the antigen by macrophages allows persistent stimulation of the immune system, activation of T lymphocytes and production of lymphokines, which in turn stimulate further recruitment of mononuclear phagocytes leading to granuloma formation. Further discussion of the immunopathology of granulomatous disease may be found in Chapter 39.

### Diagnosis and management

The disease should be suspected when someone who has worked with (or whose spouse has worked with) beryllium presents features of interstitial lung disease with histological findings suggestive of sarcoidosis [297]. There is no absolutely reliable test for berylliosis, although features that distinguish it from sarcoidosis include a negative Kveim test and absence of erythema nodosum, hilar adenopathy without lung changes, or uveitis. The beryllium patch test is not now recommended since it may itself lead to sensitization. The test for lymphocyte proliferation in response to beryllium sulphate using blood or bronchoalveolar lavage cells is the most reliable

test of sensitization and may also reflect severity of the disease [298–301]. Studies of tissue or urine levels of beryllium have proved disappointing, since high level may be found in beryllium workers with other disease and low levels in ex-beryllium workers with berylliosis [302]. However, the use of laser microprobe mass spectrometry to analyse the content of granulomas rather than of general lung tissue has enabled the demonstration of beryllium in the granulomas and not in those of sarcoidosis [303]. Where this highly specialized chemical test is available, it is therefore possible to increase diagnostic confidence appreciably.

Since the disease usually progresses, treatment with corticosteroids is normally advised. The dose should initially be of the order of 40mg daily and subsequent reductions guided by measurements of lung function, diffusing capacity being the most useful test. Most patients improve but few show full functional recovery and the treatment therefore needs to be continued indefinitely.

Prevention of sensitization depends on reducing the exposure of workers to as little beryllium as possible by careful occupational hygiene. A workplace hygiene standard of  $2\mu\text{g}/\text{m}^3$  is enforced in the UK and the USA, and adherence to this may prevent most cases occurring in future. However, its efficacy requires further study by surveillance of exposed workforces and it should be remembered that hypersensitivity diseases may not be dose-related, so that a single excursion above a relatively safe limit may produce sensitization in a susceptible worker.

## Other pneumoconioses

### Aluminium

Aluminium is mostly open-cast mined as bauxite ( $\text{Al}_2\text{O}_3 \cdot 2\text{H}_2\text{O}$ ), particularly in Jamaica. The ore is crushed, washed and treated with caustic soda to produce alumina,  $\text{Al}_2\text{O}_3$ , which is then reduced electrolytically after dissolution in cryolite,  $\text{Na}_2\text{AlF}_6$ . Fumes from this process, which is carried out in large vessels called pots, are responsible for pot-room asthma; this is probably due to fluoride rather than aluminium [304].

A diffuse interstitial fibrosis has been described in workers manufacturing alumina abrasives (corundum) composed of bauxite. The bauxite is ground, mixed with iron coke and melted at high temperatures, causing fumes containing both silica, mostly cristobalite, and aluminium oxide to be given off. The disease, characterized by honeycombing and a high risk of pneumothorax, has been called Shaver's disease after one of the physicians who first described it in 1947 [305]. It is possible that the condition was a variant of silicosis, probably of the accelerated type, rather than an effect of aluminium, the fumes having contained up to 30% silica. Fibrosis of the lungs has also been described in workers producing flake powder of metallic aluminium for the manufacture of fireworks, paints and armaments [306,307]. In this process, a coating of stearin was used to prevent oxide formation; when the metal was covered with either oxide or stearin it was relatively non-reactive. However, a change of process during the Second World War substituted mineral oil for stearin and this apparently allowed the reactive surface of metallic aluminium, when inhaled, to come into contact with alveolar walls and to initiate fibrosis. The doses that caused this disease were clearly very high and it seems unlikely that workers are at risk nowadays.

A report in 1962 [308] of a patient who worked in an aluminium powder-ball mill and who developed pulmonary fibrosis and progressive encephalopathy is of interest in view of the association of aluminium with the plaques in the brains of people dying with Alzheimer's disease [309]. The aluminium worker had very high levels of aluminium in his brain at death. It would seem that studies of neurological function in aluminium workers would be of interest. There has also been a report of a patient who developed alveolar proteinosis after 6 years' work as an aluminium grinder and whose lungs contained vast numbers of submicrometre-sized particles of aluminium [310], in keeping with more recent work suggesting that ultrafine particles may cause lung inflammation. The author has seen a patient who developed severe diffuse pulmonary fibrosis and died of a complicating alveolar cell carcinoma and who had a history of heavy and prolonged exposure to fume in a refinery producing aluminium from scrap. The lungs showed bronchiolitis as

well as alveolitis, suggesting an inhaled cause, although aluminium was not detectable. The cause of these episodes of disease remain unclear but arouse suspicion that exposure to substances in fume generated by the processes may sometimes have toxic effects.

In contrast to the uncertainty surrounding fibrogenic effects of aluminium, there is clear evidence of an increased risk of lung cancer in workers involved in the pot room and manufacture of the anodes in aluminium refineries. The evidence strongly suggests that this relates to heavy exposure to polycyclic aromatic hydrocarbons [311].

### Antimony

Antimony is mined as ores containing oxide and sulphide radicals and is used in metallic alloys, paints and pharmaceuticals. An apparently benign, non-fibrosing pneumoconiosis has been described in workers crushing the ore [312,313].

### Barium

Barium is mined mostly as barytes, barium sulphate, and may be used in the production of paints, rubber and glass, and as a drilling mud in the oil industry. Miners may be exposed to quartz dust and are at risk of silicosis [100]. In contrast, workers grinding barium salts develop strikingly dense micronodular radiological shadows without any functional abnormalities (Fig. 54.28). This benign, non-fibrosing pneumoconiosis is called baritosis [314,315]. The radiographic changes tend to disappear when exposure ceases and there is no functional abnormality associated with them [316].

### Carbon

Workers exposed to dust from graphite and carbon pigment may develop a form of pneumoconiosis indistinguishable from that afflicting miners of high-rank coal. Simple nodular changes and PMF have been described [317,318], and there is also evidence of some impairment of lung function in relation to exposure to carbon black [319].

Carbon fibres are now finding wide applications in industry and may be very fine and durable. While no problems have been described in workers, as with all such fibres care should be exercised in their use.

### Polyvinyl chloride

The best-known hazards of polyvinyl chloride (PVC) manufacture are acro-osteolysis of the fingers and angiosarcoma of the liver due to exposure to vinyl chloride monomer [320,321]. However, a low category of

**Fig. 54.28** Dense micronodular shadows of baritosis in a barium grinder.

radiological pneumoconiosis has been described in some workers and lung macules containing PVC have been demonstrated pathologically and experimentally [322–324]. It seems likely that this is a non-progressive and benign condition. Lung function changes, particularly a low  $DLCO$ , that have been described in some workers with normal radiographs were probably due to high exposures to the monomer before controls were introduced rather than to the polymer [325].

#### **Silicon carbide**

Silicon carbide is of historical interest as Carborundum, an early US invention that saved many lives because of its use as a substitute for sandstone in knife grinding. It is widely used as an abrasive and now also used in the manufacture of synthetic fibres, known as silicon carbide whiskers. There has been a report of the development of what seems to have been a benign pneumoconiosis in two workers exposed to silicon carbide dust in refractory brick works [326]. Perhaps of more concern is the demonstration in rats injected with the fibres intrapleurally of a possible neoplastic risk [270]. A study of a cohort of silicon carbide production workers exposed *inter alia* to fibres has shown a significant increase in risk of non-malignant respiratory disease and a possible increase in risk of lung cancer [327].

#### **Tin**

Tin miners are at risk of silicosis and, if exposed to radon daughters, lung cancer [328]. Tin refiners may inhale the fume from the smelting process and develop a highly radiodense but entirely benign fine nodular pneumoconiosis. The condition has been called stannosis [329,330].

#### **Tungsten carbide (hard metal) and cobalt**

Tungsten carbide is produced, usually alloyed with cobalt and other metals, for materials requiring great hardness and resistance to heat. Pulmonary fibrosis, airways obstruction and granulomatous (giant cell) interstitial pneumonitis have been described in tungsten carbide workers [331,332]. It is probable that all these reactions are the result of inhaling the cobalt, which dissolves in coolants used in the process of grinding the hard metal [333,334]. The same syndrome has been described in diamond polishers exposed to a cobalt aerosol [335]. Ionized cobalt combines with proteins to form a hapten and has long been known as a cause of skin sensitization.

The disease presents with dry cough and breathlessness and appears to be more common in non-smokers. Inspiratory crackles may be heard and diffuse fine reticulonodu-

lar infiltrates may be seen radiographically. Detected early, the condition may remit either on cessation of exposure or following a course of corticosteroids. If exposure continues, progression to diffuse interstitial fibrosis and cor pulmonale may occur. There has been a report of a patient in whom fatal giant cell pneumonitis recurred in the transplanted lung even though exposure to hard metal had ceased [336].

In some subjects a syndrome of reversible airflow obstruction may occur. This seems to be an asthmatic response to cobalt (and sometimes also nickel) and has been reproduced by challenge testing [337,338]. Mixed patterns of asthma and interstitial disease may occur.

### **Occupational bronchitis**

The interrelationships of occupational dust and fume exposure and clinical evidence of bronchial disease and airways obstruction have been the subject of some controversy. While it is rarely possible to recognize a distinct disease in individuals that can be called occupational bronchitis, exposures to dust and fume may increase the risk of these conditions occurring in exposed workers, whether they smoke or not. For example, an increased prevalence of chronic productive cough and of impaired expiratory flow rates has been recorded in coal-miners [40,46,47], gold-miners [121], foundry workers [339], cement workers [261], grain workers [340,341], asbestos miners [207] and coke oven workers [342]. Evidence that the reduction in lung function is related to cumulative dust exposure has been obtained from studies of South African gold-miners [121] and British coal-miners [56], while a relationship between dust exposure and prevalence of pathological emphysema in coal-miners suggests one possible mechanism [48]. There is some evidence of somewhat different patterns of response to dust inhalation in smokers and non-smokers; smokers develop classical airflow obstruction, with relatively greater reduction in FEV<sub>1</sub>, while non-smokers tend to develop a reduction in both FEV<sub>1</sub> and FVC, suggesting a restrictive component [343].

Although these effects have been studied in greatest detail in coal-miners, it seems likely that the effect of dust on lung function may be a general one, possibly mediated through an alveolitic and elastolytic response of macrophages and polymorphs to the dust. It is not surprising to the author, who has visited many workplaces, that prolonged exposure to dust and fume could cause, via either bronchial irritation or alveolar inflammation, chronic sputum production and airflow obstruction, resulting in an increased prevalence of such conditions in a population. In such circumstances, as with cigarette smoking, the average effect is small but the distribution of responses in the population as a result of differences in both susceptibility and exposure may result in a few

people developing clinical disease. If, as is likely, susceptibility to the irritants inhaled from cigarettes is the same as that to other irritants, it would be expected that this effect would show mainly in smokers, especially when one considers that such effects are likely to be additive. Therefore in any dust-exposed population, one might expect to see an excess of people with disease compared with a non-dust-exposed population while in individual cases being unable to point firmly to dust as a cause. In addition, if exposures to industrial dust or fume are generally controlled, it would nowadays be unusual to see non-smoking individuals with purely dust-induced disease. This gives great opportunities for sceptics to deny that prolonged inhalation of such substances is in any way harmful, an attitude usually coloured by a need to be dogmatic in front of a judge or jury who prefer to hear that diseases have only one cause. However, a more important consideration is that such an attitude leads to a denial of the need for employers to take preventive action. Application of a precautionary principle should lead one to conclude that exposure to dust and fumes generally in industry has the potential to harm the lungs and that the exposures of workers should be minimized.

## **Organic dust diseases**

### **Occupational asthma and allergic alveolitis**

These conditions are considered in detail in Chapters 34 and 37 respectively.

### **Byssinosis**

Byssinosis is a term applied to a complex of symptoms associated with the manufacture of cotton, flax and hemp [344–347]. Cotton, after picking, is cleaned and the lint separated from the seed by a process known as ginning. The lint is compressed into bales, which are then opened out by machines in a blowing room. Cleaning these machines is a very dusty job. The cotton fibres are then combed out, or carded, twisted into threads and woven. Carding and stripping the carding machine is also very dusty work. Flax is separated from the plant stems by retting (rotting, by bacterial or fungal action) followed by beating. The fibres are then carded and drawn through gills prior to spinning and weaving. Similar processes are used in the production of hemp and jute, though there is little evidence that the latter fibre is associated with byssinosis.

### **Acute effects of cotton exposure**

Up to one-third of people exposed to cotton dust for the first time develop an acute airway reaction with often

substantial fall in FEV<sub>1</sub> [348]. This is more likely to occur in atopic subjects and people with asthma and is associated with increased bronchial reactivity. It probably means that workers who develop this syndrome tend to leave the industry and that those who remain, some of whom later develop byssinosis, contain a relatively smaller proportion of atopic subjects [345].

The classical description of byssinosis is of a worker in a dusty area developing, usually after at least 10 years in the industry, a sensation of oppression in the chest or difficulty in breathing on the first day of the working week. A slight rise in temperature may also occur, as may cough and wheeze. The symptoms usually occur after about 2–4 h of exposure and clear some time after going home. No radiological changes occur. As the condition progresses, the symptoms may arise on subsequent working days, ultimately becoming permanent. However, longitudinal studies have shown that this progression from first day through to more persistent symptoms is not invariable, and that some workers start with symptoms on a daily basis while some even show remission despite continuing exposure [349]. For epidemiological purposes these symptoms have been used in the following classification of the disease.

- Grade 0: no byssinosis.
- Grade 0.5: occasional chest tightness on the first day of the working week.
- Grade 1: chest tightness on the first day of every working week.
- Grade 2: chest tightness on the first and following days of every working week.
- Grade 3: grade 2 symptoms accompanied by evidence of permanent incapacity from diminished exercise tolerance and/or reduced ventilatory capacity.

Lung function studies have shown declines in FEV<sub>1</sub> both throughout a shift and throughout the week, the change over a shift being greatest on the first day [350,351]. Longitudinal decline in FEV<sub>1</sub> has been suggested by finding lower levels of lung function than predicted in cotton workers [352], although how far these are due to smoking and how far to cotton dust remains undecided. There is evidence that those workers who show declines in lung function over a shift are most likely to show a progressive change over several years [353]. Bronchial reactivity is increased in most workers with byssinosis and falls in indices of small airways disease have been taken to suggest that the physiological response may begin in peripheral airways and that byssinosis may be regarded as a form of occupational asthma [354,355].

In the light of newer studies of the natural history and functional effects of byssinosis, the World Health Organization has proposed a new grading system for the disease (Table 54.4).

**Table 54.4** The World Health Organization grading system for byssinosis.

Grade 0	No symptoms
<i>Byssinosis</i>	
Grade B1	Chest tightness and/or shortness of breath on most of first day back at work
Grade B2	Chest tightness and/or shortness of breath on the first and other days of the working week
<i>Respiratory tract irritation</i>	
Grade RTI1	Cough associated with dust exposure
Grade RTI2	Persistent phlegm initiated or exacerbated by dust exposure
Grade RTI3	Persistent phlegm initiated or made worse by dust exposure, either with exacerbations of chest illness or persisting for 2 years or more
<i>Lung function</i>	
<i>Acute changes</i>	
No effect	A consistent decline of <5% (or an increase) in FEV <sub>1</sub> over a work shift
Mild effect	A consistent decline of 5–10% over the work shift
Moderate effect	A consistent decline of 10–20% over the work shift
Severe effect	A decline of 20% or more over the work shift
<i>Chronic changes</i>	
No effect	FEV <sub>1</sub> at least 80% of predicted
Mild to moderate	FEV <sub>1</sub> 60–79% of predicted
Severe	FEV <sub>1</sub> <60% of predicted

FEV<sub>1</sub>, forced expiratory volume in 1 s.

### Chronic effects of cotton exposure

This subject remains controversial. It is certainly the belief of many doctors in cotton and flax milling areas that some workers become permanently disabled by byssinosis. Cough and sputum are found more frequently among cotton workers than among controls [356] and ventilatory function tends to be impaired [357]. Several studies have shown a progressive decline in workers' FEV<sub>1</sub> in relation to exposure to cotton dust, in some cases of a dramatic degree [358,359]. Some of these declines are such that one would anticipate a very poor survival rate among these workers. However, mortality studies have shown either no or only small effects on mortality from chronic respiratory disease [360–362], suggesting that they may be flawed.

Necropsy studies of cotton workers with byssinosis have failed to show any distinctive pathological features [363]. There is some evidence that cotton workers have mucous gland hypertrophy and increased bronchial

smooth muscle but nothing to suggest that they suffer an excess of emphysema, either pathologically or physiologically [364,365].

### Pathogenesis

The prevalence of byssinosis varies from mill to mill, although the condition occurs in many different countries, including the UK, the USA, Indonesia, Sudan and India, being more prevalent in developing than developed countries [366,367]. The common factor seems to be the raw fibres, this material always being contaminated by fungi and Gram-negative bacteria. Fungal overgrowth may be responsible for weavers' cough and Gram-negative bacterial endotoxin for mill fever. Some types of cotton appear to be worse than others, while the earlier and dustier parts of the production process tend to cause more disease [368]. Washing of cotton reduces its effects in experimental studies [369].

The effects of inhalation of extract of cotton dust, namely chest tightness, cough, some fever and fall in FEV<sub>1</sub>, have some of the features of asthma and allergic alveolitis without being typical of either. The delayed onset after challenge is similar to that of allergic alveolitis, although the functional change differs. The symptoms and reduced response on subsequent days are similar to those described in some episodes of humidifier fever [370]. It seems likely that some component of cotton bract or its fungal and bacterial contaminants is responsible, though the mechanism of this has been much debated. Early suggestions that the action is a direct one on mast cells, causing release of histamine and other mediators of smooth muscle constriction, now seem too simplistic [371]. Similarly, evidence for an antigen-antibody reaction is unconvincing, although atopic subjects do seem at slightly greater risk [372]. Inhalation of cotton dust has been shown to lead to a neutrophil response in airways, probably due to a lipid fraction of bacterial cell walls, and it may be that release of leukotrienes and platelet-activating factor by these cells plays a part in causing the disease [373]. Similar mechanisms have been invoked in the causation of asthma, pulmonary fibrosis and emphysema, diseases with very different clinical features, so this apparent explanation of the disease is really only a framework for further research. It is probable that the reaction in byssinosis is confined to the airways and is due to larger, non-respirable dust particles. Perhaps the electrostatic charge on cotton dust is also important in determining the site of action. Much more work, in both epidemiology and the study of basic mechanisms of bronchial inflammation, is necessary before byssinosis is fully understood.

### Prevention and management

In the absence of knowledge of the precise cause, most

attempts at control of the problem have concentrated on reducing the dust exposure of workers by enclosing machinery, ventilation and, where necessary, use of respirators. Attempts have been made to reduce the hazard by removing the soluble fraction of raw cotton by washing or steam treatment [374], although these have proved either impracticable or ineffective. In the case of steam treatment, the hazard appeared to be transferred to workers in the later stages of the process. Exclusion of very sensitive workers at an early stage is necessary and transfer of workers developing early symptoms to less dusty work is desirable. Exclusion of atopic subjects is probably of little importance, although increased susceptibility of such people to the early acute bronchoconstrictive reaction results in most leaving the industry before developing classical byssinosis. Primary prevention therefore depends on the difficult process of dust control, in accordance with national legislation on dust standards. Since byssinosis is primarily a bronchial disease, it is logical that such standards should be based on inhalable rather than respirable dust measurements and the present standard in the UK and USA takes account of this (0.5 mg/m<sup>3</sup> measured as inhalable dust, less the coarse component known as 'fly').

Once the condition has developed, some symptomatic relief may be obtained by the use of inhaled bronchodilators and steroids if removal from the workplace proves impracticable. In the UK, industrial injuries benefits are available to victims of the disease.

### Humidifier fever and related syndromes

A variety of patterns of illness has been described in people working or living in buildings with humidifiers and air conditioners. The original descriptions from the USA were of typical extrinsic allergic alveolitis, and thermophilic actinomycetes were isolated from the systems [375,376]. Since then, typical allergic alveolitis and asthma have also been described in a few individuals in British offices [377,378] and cases of allergic alveolitis due to various bacterial contaminants of nebulizers and humidifiers continue to be reported [379,380]. More characteristically, British outbreaks have consisted of episodes of malaise, fever and sometimes breathlessness, often associated with non-specific aches, occurring predominantly on the first day of the working week [381-384]. Occasionally, falls in diffusing capacity or peak flow rate have been described and the syndrome clearly has overlaps with both allergic alveolitis and occupational asthma. Usually the chest radiograph is normal and physical signs are absent from the lungs.

The common factor in all these outbreaks is the presence of profuse microbiological contamination of the humidifier system. Water and air entering the system convey microorganisms that then recirculate in the water and

reproduce in sumps and on baffle plates. In such circumstances it is commonplace to find a thick jelly-like deposit on baffle plates; culture of this and of the water in the sump reveals many bacteria and fungi, together with more complex organisms such as amoebae, *Paramecium* and worms. Precipitating antibodies to the jelly and to extracts of the water are commonly present in exposed workers, whether affected or not, although recent evidence suggests that the presence of high levels of IgG antibody to humidifier water are associated with the more severe symptoms of fever, headache and chest tightness [385]. There has been much debate as to which organisms are responsible and what mechanisms are involved; amoebae, or the Gram-negative bacteria on which they feed and whose antigens they contain, have been thought to be important [386,387]. However, it seems likely that different syndromes may be related to different organisms or combinations of organisms. The mechanisms remain unresolved, though the striking similarity of humidifier fever to byssinosis has been noted [370]. It is of interest that the air conditioner was actually invented to control the temperature and humidity in cotton mills in the USA.

As far as is known, typical humidifier fever does not progress to a disabling type of lung disease and is often regarded by its victims as a 'Monday morning feeling'. Nevertheless while some of those exposed are unaffected, others may suffer more severe malaise and breathlessness. Diagnosis is made from the typical history and from the finding of a source of contaminated aerosol. Control of the problem usually requires very frequent cleaning of the systems or, preferably, change to either steam injection or the use of fresh unrecirculating water. Biocides and the use of ultraviolet light have so far proved disappointing. The efficacy of control measures may be tested by measuring antibody in the blood of exposed people or, in some outbreaks, by measurement of peak flow rates in sensitized workers.

Similar syndromes to humidifier fever have been described in cotton mills (mill fever), grain silos (grain fever) [388], piggeries (swine confinement fever) [389] and sewage works (sewage sludge fever) [390]. It is possible that Gram-negative bacterial endotoxin is responsible for these reactions. Cotton and grain workers are also at risk of the more typical features of byssinosis and occupational asthma.

Apart from the more dramatic features of humidifier fever, workers in modern offices may complain of non-specific symptoms such as headache, nasal stuffiness and general malaise. Such outbreaks have been given the rather unsatisfactory name of 'sick building syndrome' [391]. They seem to be related to a design of building intended to save energy, with little natural ventilation and much recirculation of air. Occasionally, complaints from workers have reached such a pitch that buildings have

had to be closed until their ventilation systems have been redesigned.

Finally, it should be noted that water droplets from humidifiers and cooling towers may occasionally be a source of *Legionella* infection in people working in or even visiting offices and other buildings. This disease is discussed in Chapter 13.

## Toxic gases and fumes

A wide range of gases and nanometre-sized particles (fumes) may cause toxic effects on the lung and other organs if inhaled. In general their effects may be mediated by asphyxiation, local irritation, toxic absorption and allergy. All save the last are discussed here and the most common of these substances are shown in Table 54.5.

### Asphyxiant gases

Asphyxiation may occur as a result of exclusion of oxygen from the air by physiologically relatively inert gases or by interference with oxygen transport within the body by inhalation of metabolic poisons. The important simple asphyxiants are carbon dioxide, nitrogen and methane, which may all be encountered in unventilated mine workings and after fires. Carbon dioxide causes hyperventilation, sweating, headache and vasodilatation, with loss of consciousness, a syndrome familiar to chest physicians used to dealing with patients with chronic airways obstruction. Unconsciousness occurs rapidly and often unexpectedly when breathing nitrogen as the oxygen concentration falls to about 10%. Methane has a similar effect. It is an important problem in mines, where it may accumulate as a result of decaying vegetable matter and is released spontaneously from the coal seam. Unlike carbon dioxide, it is lighter than air and loss of consciousness may occasionally save a worker's life. Explosion is the other serious hazard associated with methane.

Management of asphyxiation depends on removal of the victim and administration of oxygen. Unfortunately, industrial accidents often produce multiple casualties, as would-be rescuers are themselves overcome by hypoxia. Self-contained breathing apparatus should be available to all workers at risk of such accidents; in most countries all miners are issued with simple oxygen-generating apparatus (self-rescuers) for use in an emergency.

The important toxic asphyxiants are carbon monoxide, phosphine, cyanides and hydrogen sulphide. Carbon monoxide is a product of incomplete combustion and is encountered classically in fires, around blast furnaces and in underground mines. It is colourless, odourless and lighter than air. It combines not only with haemoglobin (with an affinity some 200 times that of oxygen) but also with myoglobin and cytochrome oxidase, as well as shifting the oxyhaemoglobin dissociation curve to the left and

**Table 54.5** Toxic fumes and gases.

Agent	Main occupations	Occupational exposure standard*
<i>Asphyxiants</i>		
Acrylonitrile (vinyl cyanide)	Plastics, rubber	2 ppm (MEL)
Carbon dioxide	Mining, tunnelling	5000 ppm
Carbon monoxide	Mining, foundry	50 ppm
Hydrogen cyanide	Plating, fumigation	10 ppm (MEL)
Hydrogen sulphide	Sewage, tanning, gas making	10 ppm
Methane	Mining, tunnelling	O <sub>2</sub> > 17%
Nitrogen	Mining, tunnelling	O <sub>2</sub> > 17%
Phosphine	Fumigation	0.3 ppm (STEL)
<i>Irritants</i>		
Acrolein	Plastics, rubber	0.1 ppm
Ammonia	Fertilizer, refrigeration	25 ppm
Cadmium fume	Alloying, welding	0.025 mg/m <sup>3</sup> (MEL)
Chlorine	Bleaching, chemicals, disinfecting	0.5 ppm
Formaldehyde	Paper, photography, preserving	2 ppm (MEL)
Hydrogen chloride	Chemicals, dyes	5 ppm (STEL)
Hydrogen fluoride	Etching, oil refinery	3 ppm (STEL)
Nitrogen dioxide	Welding, farming	3 ppm
Osmium tetroxide	Alloys	0.0002 ppm
Ozone	Welding	0.2 ppm (STEL)
Phosgene	Dyes, chemicals	0.2 ppm
Sulphur dioxide	Bleaching, smelting	2 ppm
Vanadium pentoxide	Chemicals, alloys	0.05 mg/m <sup>3</sup>
<i>Toxic absorption</i>		
Arsine	Smelting, refining, scrap metal work	0.05 ppm
Copper fume	Welding	0.2 mg/m <sup>3</sup>
Lead fume	Refining, batteries	0.05 mg/m <sup>3</sup>
Mercury fume	Electrolysis	0.025 mg/m <sup>3</sup>
Zinc oxide fume	Welding	5 mg/m <sup>3</sup>

\*Occupational exposure standard in UK, expressed as 8-h time-weighted average except where indicated. These values are subject to regular revision and should be taken as a general guideline only.

MEL, maximum exposure limit, measured over 10 min, that must not be exceeded.

STEL, short-term exposure limit, measured over 10 min.

impairing oxygen uptake into mitochondria [392]. The first symptom of carbon monoxide poisoning is usually headache and general malaise, which occurs with carboxyhaemoglobin concentrations around 10%. Such symptoms may persist for prolonged periods in people exposed to low concentrations of the gas from defective gas apparatus and are frequently disregarded or misdiagnosed by doctors. Higher concentrations lead to dizziness, nausea, weakness in the limbs and, at about 30%, clouding

of consciousness. Death in fit people occurs at carboxyhaemoglobin concentrations of about 50%, though lower levels may be fatal in people with coronary artery disease or if oxygen demands are higher, as during exercise. Long-term sequelae may include myocardial and cerebral infarction; in about 10% of survivors, a neuropsychiatric syndrome occurs that may include extrapyramidal signs due to damage to basal ganglia, amnesia and psychotic symptoms [393–395]. Management of carbon monoxide poisoning depends upon removal of the victim and administration of 100% oxygen. Use of a hyperbaric chamber is desirable if one is available and is advisable if the patient has been unconscious, even if recovery has occurred, in order to prevent the neurological complications.

Cyanides act by blocking the cytochrome oxidase enzyme system, preventing access of oxygen to the tricarboxylic acid cycle. They may be encountered in industry as hydrogen cyanide gas or as inorganic cyanates in metal refining, plating, laboratories and fumigation. In addition, vinyl cyanide (acrylonitrile) is a gas used in the production of synthetic rubbers. Exposure to these gases causes rapid onset of dizziness, nausea and tachypnoea; these symptoms usually serve as a warning so that the worker can escape, but if ignored unconsciousness and death ensue very rapidly. Treatment should be available in any sites where exposure may occur; the traditional kit consists of amyl nitrite for immediate inhalation and sodium nitrite with sodium thiosulphate for intravenous injection. The nitrites combine with haemoglobin to form methaemoglobin, which in turn reacts with cyanide to form cyanmethaemoglobin; this then combines with thiosulphate to form harmless thiocyanate. This reaction reduces the oxygen-carrying power of the blood because of the formation of methaemoglobin and is also less effective for treatment of vinyl cyanide poisoning. Thus the preferred treatment is usually to neutralize the cyanide by intravenous injection of dicobalt edetate, 150 mg of which contains sufficient cobalt to deal with 40% of an LD<sub>50</sub> of cyanide. Up to 600 mg may be given slowly, each 300 mg being followed by 50 mL of 50% dextrose to reduce risks of the anaphylactoid side-effects of the cobalt [396]. Clearly the patients should be removed from exposure by rescuers wearing self-contained breathing apparatus and given oxygen in high concentrations.

Hydrogen sulphide is also an inhibitor of the cytochrome oxidase system and is as rapidly fatal as cyanides. It is heavier than air and has the characteristic smell of rotten eggs, although olfactory accommodation occurs rapidly so that high concentrations may not be noticed. Fatal exposures have occurred in industry, in tanning, fish processing, chemical waste disposal and natural gas production [397–399]. Survivors may develop pulmonary oedema several days after exposure. Low-level exposures are associated with conjunctivitis and

keratitis and various neurological syndromes. Treatment of hydrogen sulphide poisoning requires removal from exposure, administration of oxygen and of amyl nitrite and intravenous sodium nitrite, which combine with sulphide to form sulphmethaemoglobin. Ventilatory support may be necessary for delayed pulmonary oedema and hyperbaric oxygen may help to prevent long-term neurological sequelae.

Phosphine ( $\text{PH}_3$ ) is a gas used mainly in the fumigation of grain; it is introduced into cargoes in the form of tablets of aluminium phosphide, which react with water to produce the gas. Accidental poisoning of workers, particularly grain inspectors, has been described as a result of entering the holds of ships or rail freighters holding fumigated grain [400,401]. The gas poisons intracellular oxygen transport mechanisms and manifests effects particularly on heart and liver. Cardiac failure and dysrhythmias are common complications of poisoning. There is no antidote, treatment being symptomatic.

### Irritant gases and fumes

Irritant gases injure the respiratory tract by causing acute inflammation when inhaled in high concentration. The main site of injury depends on the solubility of the gas, the more soluble gases exerting maximal effects more proximally. It is probable that the consequences of inhalation of irritant gases are non-specific to the particular chemical and that any one or more of a spectrum of adverse effects may follow exposure to any such gas when inhaled in sufficient concentration. Short-term reactions include cough, wheeze, acute bronchoconstriction, tracheobronchitis and laryngeal or pulmonary oedema. These may be followed by temporary or persistent bronchial hyperreactivity with a syndrome indistinguishable from bronchial asthma, often called the reactive airways dysfunction syndrome (see Chapter 36). In some subjects, airways obstruction is much less reversible and resistant to antiasthma treatment, suggesting the development of obliterative bronchiolitis.

Although this alarming array of consequences may follow acute exposure to toxic gases, fortunately in most cases complete recovery is the rule. Such episodes of gassing are not rare, and represent one of the more common causes of reports to the UK SWORD project, 1180 having been reported between 1990 and 1994 [402]. The most common agents in this series were chlorine, nitrogen oxides, phosphine, perchloroethylene, sulphur dioxide and trichloroethylene. In a further study of these data, some 70% of patients with acute exposure to irritant gases had recovered and were back at work within a week but 12% still had symptoms 1 month later, of whom about one-quarter had symptoms of asthma/reactive airways disease. It is intuitively obvious but not clearly established that the greater the exposure in terms of duration and con-

centration to a given irritant, the more likely the occurrence of longer-term sequelae. However, the nature of these episodes, which are always accidental and sporadic, means that only rarely have appropriate studies been carried out to observe the natural history of the condition. In the author's experience, which like all experience may be misleading, sometimes quite minor exposures may lead to persistent asthmatic or other respiratory symptoms [403], while in other cases major exposures with severe immediate reactions lead to full recovery. All such episodes should therefore be treated seriously and the use of corticosteroids to suppress persistent inflammation at least considered.

### Ammonia

Ammonia ( $\text{NH}_3$ ) is a highly irritant, soluble alkaline gas with many uses in industry. Much is used in the production of fertilizers, as well as in manufacture of synthetic fibres and plastics, explosives, nitric acid, refrigerants, pharmaceuticals and oil refining. Accidental exposure to high concentrations results in intense irritation of eyes, nose and throat with stridor due to laryngeal oedema [404]. The soluble nature of the gas results in direct damage to proximal mucous membranes rather than to more distal parts of the lung. Death may occur through asphyxia. Management involves removal of the victim and maintenance of oxygenation for the 2–3 days until laryngeal oedema settles; this may require tracheostomy. Weakly acidic eye and mouth washes may give some symptomatic relief initially. Full recovery usually ensues, although persistent cough, bronchiolitis obliterans and bronchiectasis have been described as sequelae [405].

### Chlorine

Chlorine is a heavy gas, less soluble than ammonia, used in the manufacture of alkalis, bleaches, plastics and solvents, as well as being used as a sterilizing agent. Many industrial accidents following spillages and crashes of transporters have been described [406,407]. The acute effects of inhalation are choking, chest pain and dyspnoea. Pulmonary oedema may occur immediately or after a delay of several hours, with inspiratory crackles, frothy pink sputum and radiographic changes. Management is that of non-cardiogenic pulmonary oedema; the role of corticosteroids is not established but most clinicians would probably use them. Follow-up studies of survivors of chlorine inhalation have shown equivocal results, usually confounded by ignorance of previous respiratory health and by high prevalences of smoking [408–411], but which are probably partly related to the observation made above that only a small proportion of people exposed actually develop long-term effects. Exposures to low levels of chlo-

rine might be expected to provoke attacks of asthma in those with bronchial hyperreactivity [412].

### Oxides of nitrogen

Nitrogen dioxide exists in two forms in equilibrium,  $\text{NO}_2$  and  $\text{N}_2\text{O}_4$ , a relatively insoluble, brown, mildly irritating gas. Toxic exposures have occurred particularly in four circumstances: exposure to silo gases, arc welding, combustion of nitrogen-containing material and spills of nitric acid [413–415]. Silofillers' disease occurs when farm workers enter the top of a silo, usually shortly after ensilage has begun. Nitrogen dioxide may accumulate in this situation as a result of oxidation of nitrates in the silage; being heavier than air, the gas lies on the top and in pits. Arc welders may produce the gas by combination of nitrogen and oxygen in the heat of the arc. Exposure as a result of fires occurs when dynamite burns; this has caused accidents in mines [415]. A notorious episode occurred at the Cleveland Clinic in Ohio, when nitrocellulose X-ray film caught fire and caused over 100 deaths, many of which were thought to have been due to nitrogen dioxide [416]. Exposures in the chemical industry occur when nitric acid spills and reacts with organic material such as wood or paper.

The person exposed to nitrogen dioxide may only notice relatively mild nasal and throat irritation, though with heavy exposures cough and choking may occur. Such

exposures may then lead to the progressive development of pulmonary oedema over an hour or two (Fig. 54.29), which may prove fatal. Moreover, apparent recovery may be followed 2–3 weeks later by progressive breathlessness associated with fever and diffuse lung crackles. This late reaction, which may occasionally occur after a relatively minor initial episode, is due to progressive bronchiolitis obliterans, and it also may prove fatal [417,418]. The radiograph shows diffuse punctate opacities and the lung function a predominantly restrictive pattern.

There has been much debate about the effects of prolonged low-level exposure to nitrogen dioxide, such as occur in workers exposed to diesel exhausts, people living in cities with heavy traffic pollution or in people exposed to gas cookers in their homes. Experimental chamber studies have shown that effects on airways resistance and reactivity may occur in healthy people exposed over about 2 h at concentrations of up to 10 parts per million and that similar changes occur in people with asthma exposed to concentrations down to about 0.2 ppm [419]. There is some evidence that children and women living in houses with gas cookers may show increased susceptibility to pulmonary infections, increased respiratory symptoms and some reduction in ventilatory capacity [420–422].

Exposure to high levels of nitrogen dioxide should largely be prevented by appropriate education of workers. Farmers in particular should be aware of the hazards of

**Fig. 54.29** Acute toxic pneumonitis in welder exposed to oxides of nitrogen.

silos. Management of the acute attack is as for other irritant gases, and there is anecdotal evidence that early use of corticosteroids may be of benefit both in the acute stage and in preventing bronchiolitis obliterans.

### Sulphur dioxide

Sulphur dioxide ( $\text{SO}_2$ ) is a heavy irritating gas. Its solubility causes it to provoke eye, throat, laryngeal and bronchial oedema, together with pulmonary oedema in severe exposures [423]. Such industrial accidents are rare but may occur in bleaching, preservation of foods, refrigeration and chemical industries. The gas is a general atmospheric pollutant, produced by combustion of fossil fuel, and is of importance in causing deterioration of limestone buildings and contributing to acid rain. Low-level exposures may contribute to the burden of chronic airflow obstruction and bronchial symptoms in exposed workers, though the evidence for this is controversial [424,425]. Experimental chamber studies of volunteers have shown subtle effects on lung function to occur at concentrations above 1–2 ppm in normal subjects and above about 0.2 ppm in those with asthma [426–428]; the role of sulphur dioxide in ambient air pollution is discussed in Chapter 11.

### Ozone

Ozone ( $\text{O}_3$ ) is a relatively insoluble but reactive gas that may be encountered in inert gas-shielded arc welding, the chemical industry, bleaching and industrial waste treatment. It is a respiratory irritant although severe or fatal exposures do not seem to have occurred. Occupational health interest has centred upon its long-term effects, particularly on the crews of high-flying aircraft and spacecraft, who seem to suffer an excess of symptoms attributable to respiratory irritation [429]. As discussed in Chapter 11, it is an important contributor to summer air pollution episodes and there is evidence of irritant effects in experimental studies on airways in terms of provoking changes in lung function and airway inflammation at exposures over about 0.1 ppm for several hours [427,430]. Epidemiological studies have shown relationships between rises in ambient ozone concentrations, measures of respiratory illness, and even mortality from respiratory and cardiovascular diseases [431,432].

### Phosgene

Phosgene ( $\text{COCl}_2$ ) is a heavy gas that was used as a chemical weapon in the First World War. It is now used in the production of isocyanates, pesticides, dyes and pharmaceuticals. Occasional cases of acute toxicity have been described in the chemical industry and in using carbon tetrachloride fire extinguishers. It is only mildly irritant

but acts directly on the alveolar wall, causing acute pulmonary oedema [433].

## Toxic fumes and vapours

### Metal fumes

Metal fume fever is a condition characterized by a metallic taste followed by rigors, high fever, muscle aches and headache [434,435]. It follows a few hours after acute exposure to metal fumes, particularly zinc, copper and magnesium, and settles spontaneously, without sequelae, in 24 h. It occurs in welding, smelting and galvanizing. Episodes usually occur on first exposure to fumes after a break, tolerance then developing, and in this respect bears some resemblance to byssinosis and other causes of 'Monday fever'. It is probably due to chemotaxis within the lung of neutrophil leucocytes damaged by the very small ( $<1\mu\text{m}$ ) particles of metal. Recent studies of experimental zinc oxide fume inhalation have shown evidence of alveolar inflammation and release of cytokine mediators over a 24-h period following exposure [436,437], while bronchoalveolar lavage in a worker suffering from inhalation of zinc fumes has shown a lymphocytic alveolitis [438].

Metal fume may also cause direct toxic damage to the lungs and, by absorption, to other organs. A characteristic of fumes is the very small particle size, the majority being less than  $0.1\mu\text{m}$  in diameter with a high rate of alveolar deposition. Exposure to high concentrations even of relatively non-toxic substances of this size range causes an alveolitis and may lead to pulmonary oedema. This has occurred after deliberate exposure of fire-fighters and military personnel to zinc chloride fumes during training exercises [439,440]. Mercury causes a toxic pneumonitis together with neuropsychiatric symptoms [441]. Cadmium may also cause acute pulmonary oedema and renal cortical necrosis [442]. There has been debate about whether high-level or long-term low-level cadmium exposure causes fibrosis or emphysema [443,444]. There is experimental evidence that it may cause either, depending on the conditions [445], and a detailed follow-up of workers in a copper-cadmium alloy plant has shown greater physiological and radiological changes consistent with emphysema in those exposed to cadmium than in controls [446]. A mortality study has also shown a high incidence of death from chronic airways disease in such workers [447]. One unusual episode of rapidly developing emphysema after several years of exposure to cadmium at concentrations of  $150\text{--}1000\mu\text{g}/\text{m}^3$  has also been reported [448]. Vanadium exposure, encountered in cleaning oil-fired boilers and in the use of the catalyst vanadium pentoxide, is associated with an increased risk of upper respiratory and asthmatic symptoms [449,450]. A green tongue is a characteristic of acute exposure to this chemi-

cal. Manganese workers have been shown to be at increased risk of bronchitis and pneumonia [451,452] as well as extrapyramidal disorders. Osmium tetroxide is an acute respiratory irritant [453], while chromium salts may cause nasal perforation and lung cancer.

### Other fumes

The exhaust gases of diesel engines contain a complex mixture of substances, including oxides of nitrogen, aldehydes and sulphur dioxide. They are undoubtedly irritant and cause cough in exposed workers, especially if the concentrations are high because the engine is labouring or working in an enclosed space such as a mine. Studies of long-term effects on lung function have proved negative [454,455] but it would be surprising if exposure to high concentrations for prolonged periods did not have some deleterious effects.

A condition similar to metal fume fever has been described in workers exposed to fumes of heated polytetrafluorethylene (Teflon) [456], while a reaction that is probably primarily an irritant bronchoconstriction may occur in workers exposed to heated PVC [457]. This condition has been called meat-wrappers' asthma. It is not clear whether it is provoked by PVC fumes or by heated adhesives from the label being affixed to the wrapping material [458]. Trimellitic anhydride, an epoxy resin hardening agent, is a known cause of occupational asthma [459]. In addition, haemorrhagic pneumonitis and haemolytic anaemia have been described in subjects exposed to its fumes [460]. Other organic substance, such as isocyanates, may be irritant in the high concentrations that occur with chemical spills and fires. While most isocyanates used in industry are diisocyanates, the notorious episode at Bhopal in Central India, in which several thousand people died of either acute asphyxiation or chemical pneumonitis, was probably caused by the highly irritant methyl isocyanate gas [14].

### Smoke inhalation

Acute smoke inhalation is a not uncommon emergency in non-occupational settings, as well as being an occupational hazard of fire-fighters. Smoke may contain a wide range of chemicals, especially now that plastics and synthetic foams are so widely used in furnishings. Those exposed to smoke may asphyxiate due to lack of oxygen or carbon monoxide inhalation, or suffer acute tracheitis and pneumonitis due to irritant chemicals such as hydrogen chloride or isocyanates in the smoke. Acute falls in ventilatory capacity have been recorded in fire-fighters after smoke inhalation and the inhalation of smoke has been shown to cause an influx of neutrophils into the lung with subsequent impairment of macrophage chemotaxis [461]. While short-term effects are obvious, long-term effects of

smoke inhalation are less clear; although it is reasonable to suppose that repeated exposures would increase a person's risk of chronic airways obstruction, this has not yet been demonstrated convincingly [462]. A mortality study of fire-fighters in the USA has shown the expected 'healthy worker effect', but a somewhat increased mortality from non-malignant lung disease [463]. Long-term exposure in Nepal to wood smoke in huts also seems to lead to an increased likelihood of cough and sputum production [464].

### Occupational neoplasms

Mesothelioma is discussed in Chapter 43 and asbestos carcinogenicity earlier in this chapter. Occupational lung cancer was first described in the metal miners of Schneeberg [7], and subsequently in uranium miners in Joachimstal and Colorado [465,466]. The common factor in metal mining is exposure to radon daughters, which are suspended in water droplets and inhaled by the miners. Similar increased risks of lung cancer were run by tin miners in Cornwall [328], by haematite miners in Cumbria [283] and by fluorspar miners in Newfoundland [467]. The radiomimetic, mustard gas, has been shown to have a similar effect on workers producing it [468]. Lung cancer has also been shown to occur to excess in workers exposed to arsenic [469], nickel carbonyl [470], hexavalent chromates [471], bischloromethyl ether [472,473], oils in the production of isopropyl alcohol [474], fumes in aluminium refineries and coke ovens [475,476] and printing ink [477].

In almost all patients with lung cancer, smoking is the most important aetiological factor. However, there is evidence that non-smokers exposed to these carcinogens may nevertheless develop the disease and that the two risk factors at least add up and, in the case of asbestos and cigarettes, may even multiply. It has been estimated that as many as 15% of men with lung cancer might not have developed the disease had they not also had occupational or environmental exposure to a carcinogen [478]. To the clinician, this seems an overestimate but is based on a careful review of the epidemiological literature.

Other aspects of lung cancer are discussed in Chapter 41.

### Management

The diagnosis of an occupational lung disease should lead to consideration of three separate but related aspects of management: (i) the management of the patient and the condition; (ii) rehabilitation and re-employment of the patient; and (iii) prevention of the same disease in other workers [479].

The first of these involves the general principles of disease management and has been mentioned where

applicable above. The acute conditions such as asthma, allergic alveolitis and inhalation injury may respond to routine therapy but are likely to recur if steps are not taken to prevent re-exposure to the causative agent. In the diseases caused by chronic exposure, such as the pneumoconioses, specific therapy is usually not available although supportive treatment may be of help. In all such patients consideration should be given to the availability of compensation (see Chapter 61). Rehabilitation of the patient if still of employable age should include consideration of return to the previous job. Since this often implies recurrence of the condition if exposures to the offending agent are not prevented, it is necessary for steps to be taken to ensure that the management of the company are aware of the hazard to their employees and have taken appropriate steps to reduce risks. In the UK, this can be achieved by an approach to the Health and Safety Executive, who will visit the workplace and ensure that the Health and Safety

at Work Act and relevant regulations are enforced. Taking this step also ensures that other workers are protected from the same hazard.

If the patient's condition is such that employment in the same job is undesirable, the management, or the company's occupational health service if one is available, may be approached to seek redeployment. In doing this it is necessary to observe the ethical principle of not revealing confidential medical information without the written consent of the patient. Only if redeployment proves impracticable or if attempted re-employment causes recurrence should retirement on the grounds of ill-health be considered. In these circumstances the patient should be advised about the benefits available, including industrial injuries benefit. In the UK, the Department of Employment runs a scheme for advising and limited retraining of disabled people. These matters are considered in more detail elsewhere [479].

# DRUG-INDUCED LUNG DISEASE, OXYGEN TOXICITY AND RELATED SYNDROMES

ANTHONY SEATON

Until the widespread application of cytotoxic chemotherapy to patients with neoplastic disease, pulmonary drug reactions were relatively uncommon, usually occurring as occasional bronchospasm in response to aspirin or pulmonary infiltrates following nitrofurantoin. The introduction of cytotoxic drugs in particular has increased both the range of mechanisms and the frequency of pulmonary drug reactions, so that in some hospitals they are an important component of the differential diagnosis of pulmonary disease. The range of reactions is wide, from familiar simple pharmacological effects (e.g. opiates causing respiratory depression or  $\beta$ -blocking drugs causing bronchoconstriction), through less well-understood reactions (e.g. aspirin-induced asthma, eosinophilic reactions due to sulphonamides or fibrosis due to busulphan) to the infective complications of immune suppression.

Drug reactions present to the clinician as a syndrome that may be due to a number of different causes, the patient's treatment being one possibility. This chapter therefore is organized under headings denoting the main types of reaction. However, several drugs may produce different syndromes in different subjects and appear in more than one section. Table 55.1 lists the important known adverse effects on the lung of drugs grouped according to their broad therapeutic actions. For convenience, this chapter also includes some discussion of the harmful effects on the lung of oxygen and of three syndromes in which oxygen toxicity is believed to be an important component: radiation pneumonitis, paraquat poisoning and the toxic oil syndrome.

## Types of reaction

### Bronchoconstriction

#### Mechanisms

Drugs may cause bronchoconstriction in a number of different ways. The most easily understood is a direct

pharmacological effect on airway smooth muscle, as when  $\beta$ -blockers are used for the treatment of angina or as eyedrops for glaucoma [1,2]. Similar effects have been reported following anticholinergic therapy for glaucoma [3]. The best-known pharmacological cause of asthma, aspirin, probably acts through its inhibitory action on cyclooxygenase, diverting arachidonic acid metabolism from the formation of prostaglandins to the production of leukotrienes; a genetic basis for this effect has been described that involves a leukotriene (LT) $C_4$  synthase promoter polymorphism [4,5]. Other non-steroidal anti-inflammatory drugs have a similar mechanism of action, indometacin (indomethacin) being particularly potent in this respect [6]. *In vitro* studies have shown conflicting results when considering the effects of aspirin on the cyclooxygenase of platelets [7,8] but there is some evidence of an inhibitory effect, which can be blocked by sodium salicylate and which correlates with increased respiratory burst and increased killing of *Schistosoma mansoni* [9]. Interestingly, no such effect has been found with basophils or monocytes. This raises the possibility of a role for platelets in the aetiology of aspirin-induced asthma via production of arachidonic acid metabolites.

Direct irritation of airways leading to bronchoconstriction presumably via a vagal reflex may be a mechanism in the case of asthma worsening paradoxically after inhalation of sodium cromoglicate (cromoglycate) [10] or of hypotonic nebulized solutions of ipratropium bromide [11,12]. A direct action on mast cells causing release of bronchoconstrictor substances has been suggested as a cause of wheeze following administration of morphine and codeine [13], while classical type I hypersensitivity mediated by IgE is probably the mechanism of asthma and anaphylaxis following penicillin and other antibiotics [14–16]. It should be noted that a number of drugs contain the yellow dye tartrazine, which may cause exacerbation of asthma; the mechanism of this is not known [17]. Finally, the antituberculosis drug rifampicin has important effects on the enzymatic degradation of other drugs in the liver. Of particular note is its ability to reduce the effi-

Contraceptives	Pulmonary embolism	High-oestrogen pill

ACE, angiotensin-converting enzyme.

cacy of corticosteroids (and the contraceptive pill) [18]. Asthmatic patients on steroids who develop tuberculosis often require their dose of steroids to be more than doubled when rifampicin therapy is introduced. Similarly, asthmatic patients on regular xanthine therapy may require a higher dose if they need treatment with rifampicin [19].

### Drugs causing bronchoconstriction

The more important drugs causing bronchoconstriction are listed in Table 55.2. The most significant of these from a clinical point of view are the  $\beta$ -blockers and the non-steroidal anti-inflammatory drugs. Although most of the newer  $\beta$ -blockers have been promoted as being cardioselective, this can only be regarded as a relative advantage; subjects with asthma or airflow obstruction are quite liable to suffer exacerbations when treated with effective doses [1,20] and it is wiser to avoid the use of these drugs altogether. There is some evidence that atenolol is a less potent bronchoconstrictor than other drugs of this class.

\*By interfering with antiasthma drugs.

The usual pattern of response to  $\beta$ -blockers is a gradual worsening of the patient's breathlessness and a failure to respond in the normal way to treatment with  $\beta$ -agonist drugs. The subjects usually have pre-existing asthma or airflow obstruction, although it is not uncommon for symptoms to be provoked for the first time by the use of  $\beta$ -blockers. Sometimes the adverse effect of the drug persists for some months after it has been discontinued [20].

Asthmatic and anaphylactic reactions to aspirin were first described not long after its introduction to therapeutics [21,22], and a syndrome comprising asthma, nasal polyps and aspirin sensitivity has been recognized since the 1920s [23,24]. Typically, the patients are middle-aged and non-atopic; the condition may be familial and occurs in 2–4% of all asthmatic subjects [25–28]. When it occurs in children, atopic features are usually absent [26]. The order in which the three features of the syndrome occur is variable, though aspirin sensitivity usually appears after the asthma and the polyps [29]. Urticaria and anaphylaxis may sometimes occur. The syndrome appears to be related

to release of products of arachidonic acid metabolism via the 5-lipoxygenase pathway, notably  $\text{LTE}_4$  [30].

Asthmatic subjects sensitive to aspirin are often found to respond similarly or to a greater degree to other non-steroidal anti-inflammatory drugs [31] and may show increased sensitivity to histamine provocation [32]. This may cause problems in the management of pain and rheumatic conditions in asthmatic subjects. As far as possible, analgesics with minimal or no anti-inflammatory action, such as paracetamol and dihydrocodeine, and local treatment should be used in these circumstances. Paradoxically, some asthmatic subjects find that their condition improves when they take aspirin or other anti-inflammatory drugs, such as indometacin and mefenamic acid [33–36]. In selected patients these drugs may therefore have a therapeutic role.

Other pharmacological causes of bronchoconstriction are rare. A number of antibiotics have occasionally provoked asthma or anaphylaxis. Several of these, notably ampicillin, cephalosporins, tetracyclines and spiramycin, have been described as causing occupational asthma in workers exposed to them during their manufacture [15,16,37,38]. Contrast media used in radiology that contain iodine and the iron dextran compound Imferon may provoke severe anaphylactic responses. A test dose should be administered before their use, though this may sometimes fail to predict a reaction following the full dose. Hydrocortisone used intravenously or intramuscularly may occasionally have the paradoxical effect of making asthma worse [39]. This appears to occur predominantly in aspirin-sensitive subjects; the mechanism is unknown, but in one case investigated by the author occurred with the sodium succinate but not the phosphate preparation. Cromoglicate may also occasionally cause bronchoconstriction. This has usually been attributed to irritation, although occasionally very severe episodes suggestive of an anaphylactic mechanism may occur; other rare side-effects of cromoglicate, including pulmonary infiltration, urticaria, eosinophilia and nasal congestion, support the idea that true allergies may occur [40,41].

## Cough

Any of the drugs able to provoke asthma or bronchoconstriction may cause the symptom of cough. However, one group of drugs is notable for causing cough rarely if ever accompanied by bronchoconstriction, the angiotensin-converting enzyme (ACE) inhibitors [42,43]. These drugs are widely and successfully used in the management of hypertension and cardiac failure. The cough usually starts after several months of treatment and is of a dry irritant nature. It ceases within a few days of stopping the drug, and this is therefore an appropriate diagnostic test. The symptom, which is probably related to bradykinin release, occurs in 5–20% of patients treated with the drugs and

there is little benefit to be expected from changing to another ACE inhibitor. There is some evidence that administration of cromoglicate reduces the severity and frequency of cough in such patients, experimentally attenuating the response to inhaled capsaicin [44]. However, the patients can usually be transferred successfully to an angiotensin II antagonist, which does not have the same side-effect.

## Bronchiolitis obliterans

A syndrome of progressive breathlessness associated with increasing airflow obstruction has been described in patients with rheumatoid arthritis and other collagen diseases [45,46]. A proportion, though not all, of these subjects has been treated with D-penicillamine [46,47] and it now seems possible that this drug may occasionally provoke the disease; however, it is a rare condition, in one study having occurred in only 2 of about 250 subjects with reactions to penicillamine [48]. A similar syndrome has also been described in a patient with ulcerative colitis treated with sulfasalazine (sulphasalazine) and in a patient who took an overdose of L-tryptophan [49,50]. The clinical features are difficult to distinguish from those of airflow obstruction of other causes. The breathlessness is progressive, although the rate varies from a rapid progression over weeks to a slow course over years. The airflow obstruction is irreversible and may be associated with the auscultatory signs of late inspiratory repetitive crackles and a mid-inspiratory squeak. The radiograph may show diminished peripheral markings in generalized disease or consolidation in more local disease, but is often normal.

Lung function tests show reduced forced expiratory volume in 1 s ( $\text{FEV}_1$ ) and forced vital capacity (FVC) (the former to a greater extent), raised residual volume and normal total lung capacity. Diffusing capacity is typically somewhat reduced. Pathologically there is widespread obliteration by fibrous tissue of small bronchi and bronchioles, a pattern identical to that occurring occasionally after toxic gas inhalation [51] or after adenovirus infection in children [52]. Since the condition may occur in rheumatoid disease untreated by penicillamine, it may be difficult to decide on the cause. It is wiser to assume that penicillamine is responsible if this drug is being administered and to stop it, in the hope that the condition stops progressing; reversal of the airflow obstruction in these circumstances or following treatment with corticosteroids is not common but has been reported [53].

## Alveolitis

### Clinical features

Many drugs have been described as causing diffuse alve-

olitis and the spectrum of the ensuing clinical syndrome is a broad one. The patient usually presents with slowly increasing breathlessness and, sometimes, cough. Repetitive crackles may be heard in the lung and the radiograph usually shows diffuse patchy infiltration (Fig. 55.1). A raised eosinophil count may be found in the blood, and occasionally the clinical and serological features of systemic lupus erythematosus (SLE) may be present. Lung function testing reveals a reduction in diffusing capacity, sometimes associated with diminished lung volumes. In some cases this restrictive type of abnormality is associated with an obstructive pattern as well.

These features are non-specific and may give rise to diagnostic difficulty, especially if the patient is being treated for a condition that may itself cause pulmonary infiltration. It is therefore wise to consider the possibility of drug reaction in all patients presenting with diffuse lung infiltrates. In many instances, stopping the offending drug leads to an improvement in the clinical features. Further investigation is discussed in the section on diagnosis and management.

### Mechanisms

It would be misleading to imply that the mechanisms of alveolitis due to drugs were clearly understood. Different drugs may cause very different reactions, and indeed the same drug may provoke different responses in different individuals. Some reactions are clearly related to the known pharmacological effects of the drug, i.e. they are

direct toxic effects, while others are clearly the result of an idiosyncratic reaction. For the purposes of this section, the different reactions leading to alveolitis are divided into toxic, allergic and those related to drug-induced SLE.

Direct toxic effects of drugs may be mediated in several different ways. Some drugs, including bleomycin, cyclophosphamide and nitrofurantoin, have been shown to be able to cause the generation of toxic oxygen species or acrolein [54–56], with consequent lung damage. Others may act on the system whereby the lung matrix repairs itself, interfering with or increasing the formation of collagen. Again, bleomycin is known to cause proliferation of fibroblasts with increased formation of collagen [57], while penicillamine may impair collagen formation [58]; indeed this is partly responsible for its therapeutic efficacy.

Allergic reactions are the most frequently recognized mechanisms of drug-induced alveolitis. Their sporadic unpredictable occurrence, the common association with eosinophilia and, usually, lack of a relationship to dose are evidence in support of this hypothesis. Experimental and clinical studies have shown, for example, evidence of enhanced cell-mediated immunity or a T-lymphocyte alveolitis provoked by gold salts [59,60], nitrofurantoin [61], amiodarone [62] and methotrexate [63]. It is assumed that these drugs act as haptens, binding to plasma proteins in order to induce allergic reactions. However, the search for such antibodies has been singularly unsuccessful, leading to the hypothesis that the hapten may be a metabolic product rather than the drug itself [64]. It may be that differences between individuals in the ways in

**Fig. 55.1** Bilateral, predominantly lower zone, infiltrates in a patient with an acute reaction to sulphonamides.

which drugs are metabolized in the liver could thus be a partial explanation for the sporadic nature of drug reactions.

Drug-induced SLE is a rare event. Originally described in patients treated with hydralazine, it has now been recorded following treatment with many other drugs [65,66], of which the most frequently used are shown in Table 55.3. Most cases are caused by hydralazine, procainamide, isoniazid and phenytoin. The condition mimics the idiopathic disease, with joint symptoms, fever, positive antinuclear factor (but less commonly anti-DNA antibodies), malaise, together with pleuropericardial disease and pulmonary infiltrates. Renal disease and malar erythema occur uncommonly and central nervous involvement and discoid lesions are very rare. The condition resolves when the drug is stopped. The drugs presumably act on the DNA of cell nuclei, and the sporadic nature of the condition suggests that allergic factors, perhaps combined with genetically determined slow metabolism, may be responsible. However the mechanisms are unknown.

### Drugs causing alveolitis

Table 55.4 lists some of the more important drugs known to have caused alveolitic reactions. Of the antibiotics, the most frequent offender is nitrofurantoin, used primarily for long-term urinary antiseptics [67–70]. Two syndromes have been described. The more common, first reported in 1962, is an acute illness with cough, breathlessness and fever ensuing several weeks after the drug has been started. Crackles may be heard at the lung bases on inspiration, the radiograph usually shows bilateral diffuse micronodular or patchy infiltrates (sometimes with pleural effusion) and the diffusing capacity ( $DL_{CO}$ ) is reduced. There is often blood eosinophilia and lung biopsy may show infiltration with inflammatory cells and eosinophils; vasculitis may also be present. The condition usually resolves rapidly when the drug is discontinued but recurs if it is restarted. Persistence with the drug may lead to fatal pulmonary fibrosis. The more chronic syndrome presents rather insidiously with cough and dyspnoea, usually after several years of treatment. The chest film shows basal infiltrates,  $DL_{CO}$  is reduced, eosinophilia is inconstant and the course is progressive if the drug is not stopped. Other antibiotics seem to

cause pulmonary allergic reactions much less frequently, perhaps partly because they are rarely administered for such prolonged courses. Sulphonamides (Fig. 55.2), penicillin, ampicillin and para-aminosalicylic acid have occasionally been associated with acute eosinophilic pneumonitis [71–76].

Of the anticonvulsant drugs, phenytoin and carbamazepine have caused pulmonary reactions. The former drug causes a number of non-pulmonary toxic effects, including gum hyperplasia, hirsutism, acne and cerebellar ataxia; rarely it has been described as causing an allergic

**Fig. 55.2** Drill lung biopsy of patient with reaction to sulphonamides showing infiltration of alveoli with predominantly eosinophil inflammatory cells.

alveolitic reaction, with fever, cough, dyspnoea and eosinophilia [77,78]. The chest film shows diffuse interstitial shadowing sometimes with marked hilar lymphadenopathy, and occasionally generalized lymph node enlargement may cause a pseudolymphomatous syndrome [79]. Lung biopsies have shown alveolar wall and small vessel infiltration with inflammatory cells [77]. The condition resolves when the drug is stopped. A similar syndrome has been described very infrequently following the use of carbamazepine [80,81].

Several drugs used in cardiac disease may cause alveolitis. Of those used to treat dysrhythmias, amiodarone seems most frequently to have this effect [82–84]. Its action is almost certainly a direct toxic one. Radiological signs of alveolitis tend to be related to the dose, occurring in some 13% of patients on high doses and 5% of those on doses of 400mg daily, and are often associated with other toxic manifestations such as corneal deposits [85,86]. A somewhat higher proportion of subjects develop abnormalities of lung function, and the likelihood of this is increased if a pre-existing abnormality was present. Indeed, side-effects are so frequent that amiodarone is generally only used for dysrhythmias resistant to other drugs. The clinical findings are fever, cough, dyspnoea and weight loss, usually after a few months of treatment, with interstitial shadowing on the radiograph. Subjects with pre-existing radiological abnormality seem to be at greater risk [85]. The histological features also suggest a toxic rather than allergic mechanism, with hyperplasia of type II pneumocytes and accumulation of foamy macrophages within the alveolar spaces [87,88]. The drug has a very prolonged action and its withdrawal is usually followed by slow resolution of the pulmonary abnormalities, although persistent interstitial fibrosis may remain [89,90]. Use of amiodarone should take account of this dangerous

side-effect; the dose should be the minimum required to control the dysrhythmia and the pulmonary effects should be monitored by regular measurement of the diffusing capacity.

Tocainide, a drug derived from lidocaine (lignocaine) and also used for suppression of ventricular dysrhythmias, has been reported to cause alveolitis in occasional patients [91,92]. Procainamide and quinidine may cause a syndrome resembling SLE, as may the hypotensive drugs methyldopa, hydralazine and hexamethonium [65,66,93,94]. In this syndrome, the clinical manifestations are pleurisy, sometimes associated with effusion, interstitial pneumonitis with fever, cough and dyspnoea, and positive antinuclear antibodies. The condition remits if the drug is stopped and usually also responds to corticosteroid treatment.

The most frequent of the anti-inflammatory drugs to be associated with alveolitis is sulfasalazine [95–98]. This is a drug that is broken down after ingestion to sulphapyridine and 5-aminosalicylic acid, and is used in the management of ulcerative colitis. It may cause the typical syndrome of fever, eosinophilia and pulmonary infiltration. Some patients may show evidence of airflow obstruction, probably due to involvement of the small airways. Challenge testing in one case has shown the reaction to be due to hypersensitivity to the sulphapyridine moiety [96]. As well as being associated with bronchiolitis obliterans, penicillamine may occasionally cause a diffuse type of alveolitis [99,100] or a rapidly progressive and often fatal alveolar and renal haemorrhage, mimicking Goodpasture's syndrome [101]. The alveolitis may be expected to improve on stopping the drug, although the pulmonary–renal syndrome has been reported to respond to plasmapheresis and immunosuppression [102]. Gold therapy has been occasionally associated with pneumoni-

tis, rashes and eosinophilia in patients with rheumatoid disease [59,103–105]. There is some evidence to suggest that this is due to a cell-mediated immune response. It usually starts 1–3 months after initiation of treatment and has been shown to resolve on treatment with corticosteroids together with cessation of the gold therapy [104]. Gold may also provoke SLE.

The drugs most frequently associated with alveolitis are those used in the cytotoxic therapy of patients with neoplasms. In most cases it seems that they have a direct toxic effect on the lung cells, though occasionally allergic reactions may occur. Since they are often used in combination, it may not be possible to know which drug is responsible. Moreover, in some instances they may act with radiotherapy in a synergistic or additive manner to increase the likelihood of lung damage. In contrast to the non-cytotoxic drugs discussed above, the usual pulmonary injury with cytotoxic therapy is a progressive pulmonary fibrosis with relatively little of an inflammatory component and a tendency to cause irreversible lung damage.

Bleomycin and mitomycin are cytotoxic antibiotics, both of which cause progressive pulmonary fibrosis in 5–10% of patients (Fig. 55.3). Their effects generally seem to be related to age and dose and to be potentiated by radiotherapy. Bleomycin is used in the treatment of squamous carcinomas, lymphomas and testicular cancer. Lung toxicity presents as progressive breathlessness, cough and usually diffuse nodular radiographic infiltrates [106,107]. In a personally studied group of patients, half of those receiving more than 100 mg/m<sup>2</sup> showed a greater than 15% fall in DLCO, although some patients receiving less than 100 mg/m<sup>2</sup> showed an appreciable fall while others receiving more than 400 mg/m<sup>2</sup> showed none. Apart from dose, other risk factors appear to be concomitant radiation therapy or administration of high concentrations of

oxygen [108]. The histological changes are of interstitial fibrosis with metaplasia of type II pneumocytes and scanty inflammatory cells [109,110]. Bleomycin toxicity usually arrests and may regress if the drug is stopped, and there is some evidence that steroid therapy may be helpful [111,112]. Occasionally, bleomycin causes a more obviously allergic type of reaction, with fever and eosinophilia [113]. This seems more likely to be responsive to steroids. Mitomycin, which is used in treating upper alimentary tract and breast cancers, has also been described as causing pulmonary fibrosis [114,115]. The features are usually indistinguishable from those caused by bleomycin, though pleural effusions have occurred [114].

Several cytotoxic drugs that act by alkylation of DNA have been shown to cause alveolitis and pulmonary fibrosis. Busulfan (busulphan) was the first cytotoxic drug reported to have this effect [116,117]. It is used in the treatment of chronic myeloid leukaemia. The symptoms of cough, breathlessness and sometimes fever may present quite rapidly and the chest film shows bilateral infiltration [118]. Lung function shows a restrictive pattern with a low DLCO. About 5% of patients may develop this side-effect, usually after a prolonged course of treatment, often of several years. Many patients who develop lung fibrosis die, although cessation of therapy and treatment with steroids may allow recovery if the condition is detected sufficiently early [118]. The pathological changes are non-specific, with damage to type I cells, proliferation and metaplasia of type II cells and interstitial fibrosis [117,119,120]. Very similar clinical features have been described, but less frequently, following treatment with the other alkylating drugs chlorambucil [121,122], cyclophosphamide [123,124] and melphalan [125,126]. Carmustine, a nitrosourea used mainly in the manage-

**Fig. 55.3** Drill lung biopsy of patient on bleomycin therapy for end-stage lymphosarcoma showing diffuse alveolar wall fibrosis.

ment of brain tumours and lymphomas, is a more frequent cause of alveolitis and fibrosis, these effects occurring in 1–20% of patients [127,128]. The risk is related to the total dose received although, as with all these cytotoxic drugs, idiosyncratic early or acute reactions may occur [129]. In one instance, early-onset pneumonitis seems to have occurred at the site of previous lung radiotherapy, suggesting prior sensitization [130].

Pulmonary reactions leading to fibrosis have been described in association with many other cytotoxic drugs, usually when given in combination [131]. The only one of these where such reactions seem to have occurred frequently is methotrexate, a folic acid antagonist used for prolonged maintenance treatment in leukaemia and lymphomas as well as for some solid tumours. It is now used increasingly in the management of severe rheumatoid arthritis, primary biliary cirrhosis and psoriasis. The pulmonary syndrome has allergic characteristics, occurring sporadically with no obvious relation to dose. Fever, eosinophilia and pleuritis may occur in addition to the alveolitis, which usually has a granulomatous histology. Resolution usually follows cessation of therapy and institution of corticosteroid treatment [63,132–137].

Many other drugs have been described as occasional causes of a hypersensitivity type of alveolitis. Of the more commonly used, chlorpropamide, sodium cromoglicate (possibly), imipramine and amitriptyline have all caused pulmonary shadowing associated with eosinophilia [138–140]. Pituitary snuff, when produced from animal pituitaries, has been responsible for allergic alveolitis [141] and a similar syndrome has been described following recreational abuse of cocaine [142]. Aspiration of mineral oil taken as an aperient is a well-known, though uncommon, cause of patchy pulmonary fibrosis or of areas of irregular consolidation. It occurs usually in the elderly, often in association with oesophageal reflux or hiatus hernia [143]. Finally, the use of bacille Calmette–Guérin (BCG) as a tumour-suppressant drug, most notably in the treatment of bladder cancer by intravesical instillation, has resulted in disseminated disease involving lungs and other organs in a granulomatous reaction responsive to antituberculous therapy [144].

### **Pulmonary oedema**

Acute pulmonary oedema (discussed in detail in Chapter 27) may be occasionally caused by drugs, sometimes as an idiosyncratic reaction though usually in response to an excessive dose. The mechanisms are not clear but may be a direct effect on pulmonary alveolar structures or an indirect effect mediated through the central nervous system. What evidence there is suggests that the oedema is of the high-protein increased-permeability type [145,146].

The most frequent causes of drug-induced pulmonary oedema are overdoses of aspirin and opiates. Aspirin acts

to reduce prostaglandin production by inhibition of the cyclooxygenase pathway. This may have a direct effect by increasing pulmonary endothelial permeability or an indirect effect by increasing production of leukotrienes. Whatever the mechanism, patients admitted to hospital with high salicylate levels after an overdose (>40 mg/dL) are at risk of developing acute pulmonary oedema [147–149]. Fortunately the condition responds to routine management with forced alkaline diuresis, oxygen and, if necessary, assisted ventilation. Pulmonary oedema is also a frequent feature of patients admitted with an overdose of heroin or other opiates [150,151]. Again, the mechanisms are not clear and both direct and central nervous-mediated actions have been suggested. Treatment depends on the use of naloxone and assisted ventilation; recovery is to be expected in hospitalized patients.

The other drugs associated with pulmonary oedema are much less frequent causes. Sympathomimetic drugs used in high dosage for the prevention of premature labour occasionally cause the syndrome [152,153], as does hydrochlorothiazide [154,155]. The rarity of these episodes suggests an allergic mechanism. Antipsychotic drugs such as the phenothiazines and butyrophenones sometimes cause hyperpyrexia, muscle rigidity and abnormalities of the autonomic and central nervous system, the so-called neuroleptic malignant syndrome [156]; this may be associated with cardiovascular collapse and pulmonary oedema.

### **Pulmonary vascular disease**

Oestrogen-containing oral contraceptive drugs have been shown to increase the risk of pulmonary thromboembolism in women by about six to nine times [157,158], though not the risk of subsequent recurrence [159]. They may also cause an increased risk of thrombotic stroke and myocardial infarction [160]. The effects on the clotting mechanism are probably due to the oestrogen content of the pill and the risk of thromboembolism related to its dose; there is evidence of increased activity of procoagulant factors and reduction of antithrombins [161,162]. For this reason, preparations with the lowest oestrogen content consistent with efficacy are generally prescribed. It should be remembered that the increased risk of thrombosis also applies to the use of oestrogens for other purposes, such as in the treatment of prostatic carcinoma and for the suppression of lactation. There is some evidence that some cases of pulmonary hypertension may be caused by oestrogen-containing contraceptives [163]. However, the increased frequency with which this condition was recognized in central Europe in the 1950s and 1960s was probably related to the use of an appetite-suppressant drug, aminorex [164,165]. Although the drug was not shown to cause pulmonary hypertension in animals, the epidemiological evidence in humans was

strong and the drug was withdrawn. So far no other drugs have been shown to have similar effects.

### **Pleural and mediastinal fibrosis**

Fibrosis of the pleura and underlying lung is an occasional and dose-related complication of the therapy of migraine with methysergide [166,167]. The patient usually presents after several years of treatment with shortness of breath and chest pain. The erythrocyte sedimentation rate is raised and there may be loss of weight. Chest radiography shows bilateral pleural thickening, sometimes with small effusions, and biopsy shows vascularized mature collagen. The mechanism is not known, although methysergide blocks serotonin receptors. This, together with its ability to cause fibrosis of pleura, peritoneum, and cardiac valves [168], suggests an analogy with the carcinoid syndrome in which there is overproduction of serotonin and in which cardiac valve fibrosis may also occur. Interestingly, all the other drugs that have been reported to cause pleural fibrosis are blockers of neurotransmission. *Practolol* blocks  $\beta$ -adrenergic receptors and may cause pleural, mediastinal and peritoneal fibrosis, as well as involving skin, eye and joints [169,170]. *Pleuropulmonary* fibrosis may present alone, in a manner identical to that following methysergide. *Ergotamine* blocks dopamine receptors, while *bromocriptine* blocks dopamine  $D_1$  receptors and stimulates  $D_2$  receptors. Both these drugs have been shown to cause an identical syndrome of pleural fibrosis [171,172]. Hypothetically, this observation may be explained by a balance between collagen breakdown and synthesis that is controlled by messages between involved cells, whereby receptors for these messages are blocked by the drugs [173]. In the case of carcinoid syndrome, which has also been described as a cause of pleural fibrosis [174], excess production of a neurotransmitter might cause all receptors to be blocked.

With all these drugs the course of pleural fibrosis is progressive, producing a restrictive pattern of lung function. However, the condition remits when the drug is stopped and in most instances there is reduction in symptoms and some improvement in lung function, though residual fibrosis remains on the chest film (see Figs 43.12 & 43.13).

### **Other pulmonary reactions to drugs**

It should not be forgotten that drugs may cause lung disease in an indirect manner. Not infrequently hypoventilation and respiratory failure may be provoked by overdose or injudicious therapeutic use of narcotic or sedative drugs, particularly in the elderly or in those with previous airflow obstruction. On one occasion in the author's experience, the cause of a mysterious case of hypercapnic respiratory failure was discovered when the patient was found

to have been taking large doses of a traditional Edinburgh treatment for peripheral vascular disease, prescribed by a surgeon, containing narcotic doses of barbiturates and masquerading under the name of *Chief's Powder*! Respiratory failure is discussed further in Chapter 24. Drugs acting on the immune system, used in the management of cancer, transplantation and vasculitic diseases, may set the scene for opportunistic pulmonary infections; these conditions are described in Chapter 52.

## **Diagnosis and management**

The key to diagnosis of drug-induced pulmonary disease is awareness of the possibility. Most lung diseases have an external or environmental cause and it is important to exclude such possibilities in the case of alveolitis or asthma of obscure aetiology. A note should be made of all drugs taken by every patient and any drugs with unfamiliar names should be checked in reference books.

If a drug reaction seems a possibility, appropriate baseline investigations should be carried out and the drug stopped. These investigations normally include chest radiography and lung function testing, although erythrocyte sedimentation rate, temperature records and differential white cell counts may often be helpful. If several drugs are under suspicion, it is best to stop all those regarded as not essential to the patient's well-being. In the case of single drugs, cessation usually results in clinical improvement; normally this provides sufficient proof for the drug to be avoided subsequently, but if necessary when allergy is suspected a challenge test can be carried out after an interval during which the drug is not taken. This should not be performed unnecessarily as severe reactions may sometimes occur. Appropriate indications are when the drug is one of a multiple regimen and it is not clear which is responsible, or when the drug is itself a combination of two medicaments, for example *Salazopyrin* or *Rifinah*. Challenge testing should be carried out under hospital supervision and initially should use a fraction (perhaps a hundredth) of the therapeutic dose; the results should be monitored by lung function testing. It is only appropriate in suspected allergic reactions and is unlikely to be of value in diagnosing reactions due to direct toxic effects.

Lung biopsy, gallium scanning and bronchoalveolar lavage have only a small part to play in the diagnosis of these reactions, as they only show non-specific effects of a wide range of pulmonary reactions. They may of course have an important role in the differential diagnosis, by excluding other possible pathological processes. In general they are appropriately employed after drug reactions have been excluded.

Management of pulmonary drug reactions consists in stopping the offending drug and, if necessary, substituting a less harmful one. Occasionally, corticosteroid therapy

may be used though its value can only be judged by anecdotal evidence in most cases. In the management of malignant disease, pulmonary side-effects are relatively frequent occurrences and cessation of the drug may result in relapse. They are therefore an important and sometimes fatal complication of therapy. Hyposensitization, or induction of tolerance, may be tried if the drug is considered essential, all alternatives are unsatisfactory and the reaction is thought to be allergic or idiosyncratic. These circumstances must be rare with respect to drug-induced lung disease, although many older chest physicians will be familiar with the techniques for management of allergic rashes to para-aminosalicylic acid and isoniazid in treating tuberculosis. The main interest in this subject currently centres on the induction of tolerance to aspirin and non-steroidal anti-inflammatory drugs [175]. There is evidence that this may be of benefit to some patients, particularly with respect to alleviation of rhinitis. However, it should be embarked upon with great care, as serious reactions can occur [176]. There is some hope that in the future leukotriene antagonists may also have a role to play in aspirin sensitivity [177].

### Lipoid pneumonitis

Inhalation of oil is an occasional cause of lung disease. The reaction depends on the type of oil. Mineral oil remains in the lung, engulfed by macrophages, and may give rise to fibrosis; animal fats are hydrolysed by lung lipases and the resulting fatty acids cause acute inflammatory pneumonitis, while vegetable oils are relatively inert [178]. Animal and vegetable oils may enter the lungs by aspiration in subjects with hiatus hernia, oesophageal reflux or neuromuscular disease, and the former are an important cause of unresolved pneumonia in the elderly [179]. Mineral oil may be inhaled occasionally by shipwrecked mariners, but the important causes are the use of oily nasal drops or of liquid paraffin as an aperient [180–182]. The paraffin is usually taken daily over years and aspiration of small amounts regularly may cause a patchy diffuse granulomatosis leading to fibrosis [183]. A similar syndrome has been described in Guyana in people of Indian origin who smoked cigarettes made of tobacco to which mineral oils had been added as flavouring [184]. This blackfat tobacco-smokers' lung was an important cause of chronic pulmonary fibrosis, leading to much disablement and death in that country. Diffuse fibrosis at least partly due to inhaled paraffin has also been described in a fire-eating punk-rock drummer [185].

### Oxygen toxicity and related syndromes

#### Mechanisms

It may seem paradoxical that oxygen, upon which animal

life depends, has the potential to harm the lung. However, oxygen became an important component of the earth's atmosphere only after the evolution of plant life and photosynthesis, and all animals may therefore be regarded as organisms that have not only turned this gas to good effect but which have also developed mechanisms for overcoming its toxic effects. These effects depend upon the relative ease with which oxygen may be reduced by cells to produce superoxide anion ( $O_2^-$ ) and hydrogen peroxide ( $H_2O_2$ ). These radicals are toxic to cell membranes but may also react together to form hydroxyl radical ( $\cdot OH$ ) and singlet oxygen ( $^1O_2$ ), which are highly toxic and react with cellular chemicals leading to peroxidation of lipids, depolymerization of mucopolysaccharides, rupture of protein sulphhydryl bonds and damage to nucleic acids. These reactions are utilized by phagocytic cells in the destruction of invading organisms; however, when phagocytic or other metabolizing cells are damaged they may be responsible for the destruction of adjacent cells in the tissue under attack.

Clearly, the alveolar tissues are in a vulnerable position with respect to toxic damage by oxygen, since they have to provide adequate concentrations to other tissues while resisting potential harm themselves. In common with other cells, those of the lung have developed mechanisms for defending themselves against such damage; superoxide dismutase eliminates superoxide radical, catalase and peroxidases deal with hydrogen peroxide (the green colour of infected sputum is due to the presence of myeloperoxidase from leucocytes) and substances such as glutathione, uric acid, vitamin C and vitamin E mop up free radicals. Thus the normal lung is protected by a balance between production and destruction of free radicals, a balance that may be disturbed by a number of different factors.

The inhalation of high concentrations of oxygen makes more oxygen available for conversion to free radicals and this may reach the stage of overwhelming the antioxidant defences [186,187]. However, there is evidence that gradual increase of oxygen concentration may prevent this by induction of superoxide dismutase and catalase, although experimentally there appears to be a limit to the amount by which the catalase gene can be upregulated [188]. Overwhelming infection or recruitment of inflammatory cells to the lungs may similarly result in tissue damage by release of free radicals. Radiation therapy is particularly toxic to the lungs because of its ability to produce free radicals from cells in its path. Similarly, the herbicide paraquat acts by increasing production of superoxide radical in the lung.

#### Ventilator lung

Some patients requiring prolonged assisted ventilation develop a syndrome of decreasing compliance, increasing

hypoxaemia and diffuse radiological shadowing. They require increasing inspired concentrations of oxygen but with decreasing effect on  $P_{aO_2}$ . At autopsy, their lungs may present a variety of pathological appearances, including oedema, hyaline membranes, septal thickening by oedema and proliferating fibroblasts, and some interstitial fibrosis [189] (Fig. 55.4). Although in such situations it is often difficult to distinguish between the various possible causes, as there is almost always some other underlying lung disease, it is clear that hyperoxia is an important factor in the production of this damage. The condition may be reproduced in animals, where it has been shown that the sequence of pathological change consists of, firstly, an acute phase with generalized interstitial oedema, alveolar haemorrhage, capillary endothelial necrosis and damage to type I pneumocytes and, secondly, a proliferative phase in which the oedema is reabsorbed and there is hyperplasia of interstitial fibroblasts and type II pneumocytes [187]. Resolution may occur, although progressive fibrosis of the interstitial tissues is a more usual sequel in animals that survive.

Studies in humans have shown that 100% oxygen may be tolerated for up to 24h with no more than some bronchial irritation and substernal discomfort [190,191]. However, lavage studies have shown that by 18h there is early evidence of leakiness of alveoli and of liability of macrophages to release mediators of fibrogenesis [192], while physiological studies have shown falls in compliance, diffusing capacity and tracheal mucus flow rate [193–195]. It seems likely therefore that subtle changes may occur relatively early in the course of hyperoxia. However, the clinical syndrome does not usually present until after several days of exposure to high oxygen con-

centrations, the time varying inversely with the concentration. Inspired oxygen concentrations of less than 50% seem to be tolerated indefinitely [196].

The management of oxygen toxicity presents the physician with a therapeutic dilemma. Patients at risk of this problem inevitably have serious lung disease and require tissue oxygenation. Adequate inspired concentrations of oxygen must therefore be delivered to prevent hypoxic damage to other tissues. The aim should therefore be to deliver a sufficient concentration to keep the patient's blood adequately saturated but without exceeding a  $P_{aO_2}$  of about 13 kPa (100 mmHg). If this requires inspired concentrations above 50%, then this concentration has to be given, in the knowledge that far from all such patients suffer lung damage as a result and the effects of hypoxaemia are more acutely threatening. The use of appropriate methods of ventilation, such as positive end-expiratory pressure, may allow the oxygen concentration to be kept as low as possible (see Chapter 58).

Increased understanding of the mechanisms of oxygen toxicity has given rise to hope that some pharmacological therapy may eventually be helpful in the prevention of the condition [187]. Intramuscular vitamin E has been used with some success in premature infants and superoxide dismutase has been tried in paraquat poisoning [197–199]. Small doses of endotoxin have been shown to protect rats from hyperoxia, probably by increasing production of superoxide dismutase and catalase [200].

### Paraquat poisoning

The herbicide paraquat kills plants by virtue of its ability to be reduced and oxidized very readily. It is thus able to

**Fig. 55.4** Lung of patient who died after prolonged intensive care and ventilation for pneumonia of undetermined aetiology showing intra-alveolar fibrosis and hyaline membranes.

compete with NADP for electrons, becoming reduced to a stable free radical. In humans, it is able to react with oxygen within cells to catalyse the production of superoxide radical and hydrogen peroxide.

Most cases of paraquat poisoning occur as a result of accidental ingestion of the 20% agricultural preparation called Gramoxone, usually in the belief that it is lemonade [201,202]. It has also been taken with suicidal intent and deaths have been described following subcutaneous injection and after transcutaneous absorption in men employed to spray the poison [203]. Ingestion of the 20% solution is attended by a mortality of about 60%, the risk being related to the dose taken [204]. Deaths have also followed ingestion of the 2.5% paraquat in the Weedol granules commonly used by gardeners.

### Clinical features

The patient often suffers oral and oesophageal ulceration after ingestion and may complain of abdominal pains, vomiting and diarrhoea. Toxic effects on the kidneys and liver may lead to acute renal failure and jaundice, although these conditions are self-limiting and usually resolve if the patient can be helped over them without pulmonary problems. Respiratory symptoms, with increasing breathlessness and cyanosis, commence a few days after ingestion and almost always progress remorselessly [201,205]. The chest radiograph shows diffuse opacification and there is a progressive fall in oxygen saturation. The patient usually dies of irreversible respiratory failure within 2–3 weeks of ingesting the paraquat, although occasional patients who have taken lower doses may survive despite having shown evidence of lung disease [206]. There is some evidence from studies of workers engaged in spraying paraquat, and who have absorbed it in relatively small doses through the skin, that subacute poisoning can occur which may lead to chronic interstitial fibrosis, thromboses and proliferative changes in small pulmonary arteries [203]. Similar lesions have been produced in rats by application of paraquat to the skin [203].

### Pathology

The pathological appearances in humans are confused by the presence of changes that could be related to the prolonged high  $FIO_2$  that has usually been given as treatment. However, identical changes occur in rats given paraquat and kept in normoxic conditions. In animal studies, the first sign of damage is oedema and ballooning of the type I and II pneumocytes [207,208]. Within a few days these cells have been destroyed, leaving the capillary endothelial cells intact. Cells that are progenitors of fibroblasts then fill the alveolar spaces, eventually developing into mature cells. The alveoli thus become organized into a

mass of cellular fibrous tissue surrounded by intact capillaries. In humans, two pathological appearances have been noted [204]. In patients dying acutely after paraquat ingestion, alveolar and interstitial oedema with hyaline membranes is prominent. In those dying later, either intra-alveolar fibrosis or diffuse irregular fibrosis with dilatation of bronchioles causing a honeycomb appearance is seen. It is likely that these appearances represent progression rather than different reactions, analogous to the appearances found in animals.

### Management

The essential point in management is to act early. Any unabsorbed paraquat should be removed from the gastrointestinal tract by administration of fuller's earth and by gastric or bowel lavage followed by forced diuresis, haemodialysis or charcoal haemoperfusion. Management may be guided by the plasma concentration of paraquat measured by rapid colorimetric or radioimmunoassay methods. It has been shown that if the concentration does not exceed 2.0, 0.6, 0.3, 0.16 and 0.1 mg/L at 4, 6, 10, 16 and 24 h after ingestion, survival is likely [209].

If the patient presents with evidence of jaundice, renal failure or respiratory symptoms, it is almost certainly too late for effective therapy. Unfortunately, oxygen is needed by the tissues but enhances the toxic effects of paraquat. Dialysis is unhelpful at this stage since the sequence of pulmonary damage has already begun. Corticosteroids and cyclophosphamide have their advocates [210] but are probably ineffective [211]. A logical approach would be the early use of iron chelators or superoxide dismutase to antagonize toxic oxygen radicals and D-propranolol to block paraquat receptor sites [198,212]; there is one case report of survival following vigorous treatment with desferrioxamine and acetylcysteine after bowel decontamination and haemodialysis [199]. However, almost all such patients end up on a ventilator and their chances of survival are negligible. Lung transplantation has been tried but except in one case the transplanted lung itself has succumbed to the effects of residual circulating paraquat [213,214]. The very few survivors of early pulmonary damage following paraquat ingestion or intravenous injection all probably had relatively small doses, though the fact that survival has occurred in such circumstances justifies vigorous treatment [215,216]. At present, the hopeless outlook of patients with progressive lung disease requires compassionate treatment with opiates.

### Radiation pneumonitis

Irradiation of tissues causes cell death, the most actively dividing cells being those affected most readily. The effect of radiation bombardment of atoms and molecules in cells is to remove electrons. Irradiation of the water molecules

in a cell first causes the generation of an unstable ion pair,  $H_2O^+$  and an electron. These then form a hydrogen ion and a free hydroxyl radical. Further reactions result in the formation of other toxic species, including hydrogen peroxide. The presence of oxygen facilitates these reactions and high concentrations (or increased pressures) of oxygen sensitize tissues to the damaging effects of ionizing radiation [217,218]. Thus the mechanism whereby radiation may damage the lung is analogous to that of oxygen or paraquat toxicity.

As would be expected, the effects of radiation on the lung are principally on vascular endothelium and alveolar type II pneumocytes. The lung is relatively resistant to radiation up to a single dose threshold of about 6 Gy [217]. The risk of radiation damage thereafter increases sharply with increasing dose, from about 30% after a single dose of 8 Gy to 80% after 10 Gy. Higher doses may be withstood if spaced over longer intervals, with a 5% risk attending 25 Gy given over 4 weeks in 20 doses [217]. There is of course individual variability in response and other factors, such as oxygen therapy and cytotoxic drugs given simultaneously, may increase the risk [219,220].

### Clinical features

Radiation pneumonitis is relatively uncommon with

modern techniques of radiotherapy. It is usually seen following mediastinal treatment of lymphoma or breast carcinoma but may occur after treatment of lung cancer, pulmonary metastases or even radioiodine therapy for lung metastases from thyroid carcinoma [221–223]. The condition usually presents 1–3 months after treatment is started, though it may occur earlier or later (Fig. 55.5). If the radiotherapy was localized the only signs may be radiological, although more generalized effects may cause progressive dyspnoea associated with repetitive inspiratory crackles on auscultation. There may be a dry cough, and pleuritic pain may indicate a radiation-induced rib fracture. Skin changes, erythema, dystrophy and telangiectasia often indicate the site of radiation. Unless very extensive and severe, the pulmonary changes are usually self-limiting. The breathlessness usually subsides slowly, over weeks or months, though the patient is often left with some residual dysfunction and studies on dogs have shown restriction and reduced *DLCO* to be likely sequels [224]. The radiological changes in the acute stage mimic pulmonary oedema, although they are normally confined to the site of treatment. Subsequent resolution in more severe cases is marked radiologically by the development of irregular fibrosis in the affected area (Fig. 55.6). Thickened pleura and dystrophic rib changes may be visible.

**Fig. 55.5** Radiation pneumonitis that developed 6 weeks after therapy for carcinoma of the right breast. Note the demarcation between normal and damaged lung medially.

**Fig. 55.6** End results of radiation therapy for breast carcinoma. Note the absent breast, left upper zone fibrosis (a) and dystrophic changes in the anterior part of the seventh rib (b).

### Pathology

Since the pathological changes have been largely described in people who have died after a course complicated by oxygen therapy and infection [225], description of the earlier changes relies largely on studies of small mammals [226,227]. The appearances of classical radiation pneumonitis mimic closely those of oxygen toxicity, with initial vacuolation and necrosis of endothelial and type I cells, oedema in the alveoli and interstitial tissue and hyaline membranes. Capillary lumens become occluded by thrombi and there is proliferation of type II pneumocytes. The end stage is diffuse interstitial fibrosis, though if recovery occurs the normal alveolar epithelium may become regenerated. However, more recently a form of pneumonitis has been recognized in which hypersensitivity appears to play a part [228,229]. In these cases even local radiation to a part of the lung may cause a bilateral lymphocytic alveolitis demonstrable by bronchoalveolar lavage and sometimes by clinical symptoms and signs, these features ultimately resolving without fibrosis. This may well form the pathological basis of the transient pneumonitis often seen clinically.

### Management

In most instances no special treatment is required as the condition is localized and resolves spontaneously. If it is sufficiently severe to cause breathlessness, most authorities would advise treatment with high doses (40 mg or more daily) of prednisolone, gradually reducing the dose as the condition responds [230]. Care should be taken to prevent infection and any evidence of this should result in early treatment with broad-spectrum antibiotics. If hypoxia occurs, only enough oxygen should be given to restore the  $P_{aO_2}$  to about 13 kPa (100 mmHg), since high alveolar tensions may aggravate the damage.

### Toxic oil syndrome

An epidemic disease characterized by diffuse neurological and vascular damage occurred in Spain in 1981 and was caused by the ingestion of contaminated rapeseed oil thought to have been denatured by aniline, though the toxic component has never been identified [231,232]. In those with respiratory symptoms, the initial illness was characterized by dry cough, dyspnoea, pulmonary oedema, fever and rashes. There was usually spontaneous recovery after 2–3 weeks and then, in a proportion, vascular lesions and fatal pulmonary hypertension occurred. At a later stage scleroderma, neuropathies and joint contractures were the main problems, and long-term lung

involvement was not prominent [233,234]. At necropsy, intimal proliferation and medial hypertrophy were prominent in muscular pulmonary arteries, with muscularization of pulmonary arterioles [235]. Evidence of vasculitis

was also found in systemic veins and arteries. It was felt that these lesions were analogous to those occurring after radiation, suggesting that they might have been caused by the release of free oxygen radicals.

# SOME PAEDIATRIC INFLUENCES ON ADULT LUNG DISEASE

GEORGE RUSSELL

This chapter focuses on developments in our understanding and management of a few relatively common paediatric disorders that have implications for adult physicians. In the last two decades there have been major changes in the ability of paediatricians to ensure the survival of infants and children afflicted by illnesses that in the past would have proved fatal. These changes have led to the survival of many children with chronic respiratory ailments who are now entering adult life with impaired respiratory reserve. With the physiological decline in lung function that is an inevitable part of ageing, even such adults who are initially symptom-free are likely eventually to experience premature respiratory insufficiency and to have a considerable impact on adult respiratory services.

This impact has already been felt for cystic fibrosis, which enjoys the dubious distinction of being the most common recessively inherited fatal condition in populations of northern European stock, a gene frequency of 1 in 25 resulting in a disease prevalence of 1 in 2500. The prognosis for cystic fibrosis diagnosed during childhood is constantly improving, the current odds for a child born in 1983–85 entering his or her teens being just under 90% for girls and just over 90% for boys [1]. This means that the great majority of children with cystic fibrosis survive into adulthood, supporting previous estimates [2] that prolonged survival would soon be the norm. Not unexpectedly, prolonged survival has brought additional complications in its wake. In particular, diabetes mellitus and liver disease are seen with increasing frequency, with the result that the long-term care of affected individuals becomes ever more complex, posing major logistic and financial problems for adult respiratory services.

The identification of the gene responsible for cystic fibrosis has enabled accurate prenatal diagnosis following determination of the carrier status of the parents, either by initial examination of the mother's genotype followed by that of the father (sequential screening) or by examining DNA obtained from both parents simultaneously (couple screening). Whichever technique is adopted, the applica-

bility of this approach is limited by the impossibility of testing for more than a handful of the known pathological mutations in the cystic fibrosis gene and by the need to obtain genetic material from the father as well as the mother. Although prenatal diagnosis initially using amniotic fluid levels of microvillar enzymes and later specific gene testing has been available for more than a decade, there is no evidence that it has had any effect on the overall numbers of children born with cystic fibrosis in the UK [1], though the effect in individual centres has been dramatic [3]. It is therefore possible that if funding were made available for antenatal diagnosis, the numbers of affected infants might eventually fall.

Universal antenatal screening leading to termination of pregnancy raises important ethical issues. Although cystic fibrosis remains a fatal disorder, the constantly improving survival mentioned above, with further improvements such as gene therapy on the therapeutic horizon, make the case for termination much less clear-cut than was the case only a few years ago.

The other form of screening still under debate is neonatal screening, most efficiently performed by examining a blood spot for immunoreactive trypsin, followed by gene mutation analysis to eliminate the large numbers of false positives identified when immunoreactive trypsin is used alone [4]. This approach reduces the number of inappropriate treatments and investigations to which affected children are usually subjected before a diagnosis is made, and allows the family to make informed decisions regarding further procreation. Several studies have now shown that in the long term patients diagnosed by screening fare better in terms of nutrition and decline in lung function than those diagnosed clinically [5,6]. There is therefore considerable pressure to introduce universal neonatal screening, which may produce further improvements in the prognosis for affected children.

Another result of modern paediatric treatment has been the dramatic fall in neonatal mortality resulting from intensive care, which has led to the survival of increasing numbers of extremely premature infants who at one time

would have been considered previable. Unfortunately, the impressively good mortality statistics found in most neonatal units have been bought at a heavy price in neuro-developmental disability and, of interest to adult respiratory physicians, bronchopulmonary dysplasia [7], more commonly known simply as chronic lung disease.

The aetiology of chronic lung disease remains obscure, although its incidence is related to low birthweight and gestational age, the barotrauma of artificial ventilation, and oxygen administration in the neonatal period. Immature antioxidant defences may play a part; during fetal life the infant exists in a hypoxic environment and has no need of such defences, so that antioxidant enzyme systems do not appear until late in gestation [8]. The prematurely born infant is therefore ill prepared for the much higher oxygen tensions prevailing in the extrauterine world, particularly if surfactant deficiency necessitates the administration of high concentrations of oxygen.

Pathologically, bronchopulmonary dysplasia is characterized by diffuse alveolar damage with increased capillary permeability, with an infiltrate of inflammatory cells, principally neutrophils, and the release of inflammatory mediators including neutrophil elastase [9] and leukotrienes [10], which are presumably responsible for the bronchial hyperreactivity that characterizes the disorder in its later stages.

In the neonatal period, the diagnosis of bronchopulmonary dysplasia is based on respiratory distress lasting for longer than 4 weeks, oxygen dependency persisting beyond 36 weeks' postconceptual age [11] and a wide variety of radiographic abnormalities. In later infancy, laboratory assessment shows hypoxaemia and sometimes hypercarbia, associated with abnormalities of pulmonary function including increased airways resistance, air trapping with increased functional residual capacity (FRC), decreased lung compliance with increased work of breathing, bronchial hyperreactivity and, in some, pulmonary hypertension. These changes may be associated with growth failure, and it is commonly observed that the lung changes seldom improve until the child begins to thrive.

Management has tended to focus on anti-inflammatory agents such as dexamethasone [12], diuretics and the avoidance of barotrauma and hyperoxia by meticulous attention to ventilator technique. The condition tends to improve over time, and oxygen dependency seldom persists beyond the first year of life. However, functional abnormalities persist throughout childhood, with slightly impaired lung function at rest but substantial impairment of the ventilatory response to exercise and reduced aerobic capacity [13]. Few studies have been performed on adult survivors [14] but currently available information suggests that these children are entering adult life with considerably impaired lung function and exercise tolerance.

Recent improvements in the respiratory management of premature babies, such as high-frequency oscillatory ventilation and surfactant therapy, may have led to some reduction in the proportion of survivors of neonatal intensive care who have chronic lung disease [15], a benefit that may be offset by an overall increase in survival. The continuing increase in the prevalence of chronic lung disease now poses substantial financial and social burdens for society in general and affected families in particular. Zimmerman [16] cites a newspaper report estimating that in 1988 the annual cost of this condition was \$2.4 billion throughout the USA, a figure that has undoubtedly increased since then. As they appear in ever greater numbers over the next few years, the adult survivors of chronic neonatal lung disease will contribute significantly to the burden of adult lung disease.

The survival of sufferers from paediatric respiratory disease represents an obvious contribution to adult respiratory disease. More subtle are the long-term effects of environmental influences on the lungs of the unborn baby, of which the most obvious, and certainly the most extensively investigated, is maternal smoking. This is associated with a wide variety of adverse effects on the fetus, ranging from increased fetal loss by way of spontaneous abortion, stillbirth and neonatal death to growth retardation and an increased prevalence of respiratory symptoms during childhood. Data from the British Birth Survey showed that the adverse effects of smoking during pregnancy could be separated from those of passive smoking postnatally, and strongly suggested that intrauterine exposure was more important than postnatal exposure [17]. These epidemiological observations are supported by abnormalities of lung function; in two separate studies, Tager and colleagues [18] and Hanrahan and colleagues [19] have shown a decrease in maximum expiratory flow at FRC of about 50% in the offspring of mothers who smoked during pregnancy, pointing to the presence of significant airways disease. In an era when, contrary to the general trend in the UK, the prevalence of smoking is increasing in young females, the effects of maternal smoking are particularly worrying. Although the case for discouraging maternal smoking during pregnancy is overwhelming, in practice these mothers tend to stick tenaciously to their habit.

The role of intrauterine nutrition has attracted considerable interest since Barker's observations on the relationship between birthweight and the subsequent development of chronic obstructive pulmonary disease [20]. Although this study did not take account of prematurity or smoking, both of which are likely to have effects independently of birthweight, decreased lung function between the ages of 59 and 70 years and death from chronic obstructive pulmonary disease were related to low birthweight. Barker speculated that intrauterine influences which retard fetal weight gain may permanently

constrain the growth of the airways. The association of congenitally small airways with postnatal lung disease is supported by the observation of Martinez and colleagues [21] that children with evidence of impaired airway function in infancy are prone to develop wheeze in association with viral infection. Against a background of ever-increasing survival rates for premature and low birth-weight infants, these findings are a source of anxiety to neonatologists and chest physicians alike.

Interference with intrauterine lung growth also occurs in association with a variety of conditions that result in intrauterine compression or interfere with fetal breathing movements. These include the more obvious space-occupying lesions, such as diaphragmatic hernia and pleural effusion, as well as congenital lung abnormalities, such as cystic adenomatoid malformation, external compression from asphyxiating thoracic dystrophy, interference with respiratory muscle activity in spinal muscular atrophy, muscular dystrophy and anterior abdominal wall defects, and pulmonary constriction due to reduced amniotic fluid volume following prolonged rupture of membranes and renal agenesis. Studies on children who survived in previous generations suggest a relatively benign prognosis, with little interference with daily activities, although modest impairment of lung function is common [22,23] as is bronchial hyperreactivity [24]. Whether the prognosis for the current generation of children surviving more severe abnormalities with the help of high-frequency ventilation and extracorporeal membrane oxygenation will be equally benign remains to be seen, but it seems more than likely that survivors will enter adult life with more severely impaired lung function.

Even after delivery at a normal birthweight, the child's lungs are anatomically small, functionally immature and are still growing and developing. It is no great surprise therefore that they should be exquisitely sensitive to the effects of inhaled toxins and that passively inhaled tobacco smoke should have a marked effect on respiratory morbidity. The effects of passive smoking have been assessed in many studies over the years, with wide variations in the methods used to both assess exposure to smoke and define respiratory morbidity. Associations have long been established between passive smoking and pneumonia and bronchiolitis in infancy [25] and with wheeze, cough and other respiratory symptoms in older children [26,27]. Although the effects of passive smoking on lung function are less dramatic than those of intrauterine exposure to tobacco smoke, several studies [28,29] have shown significant adverse effects on lung function and growth. The overall effect amounts to a reduction in forced expiratory volume in 1s (FEV<sub>1</sub>) of the order of 5–10%. Passive smoking during childhood has also been associated with a variety of other effects during childhood, including bronchial hyperreactivity [30], glue ear and sudden infant death syndrome [31], and is said to

account for 17% of cases of lung cancer in adult non-smokers [32]. Smoking is strongly related to social deprivation, and in a recent study of Aberdeen schoolchildren we were unable to detect any effect of deprivation on respiratory morbidity that could not be explained by parental smoking.

Childhood infections also have important long-term effects on the lungs. In the past, measles and whooping cough were responsible for many cases of bronchiectasis, although this problem has now all but disappeared with the advent of successful vaccines for these conditions. These days, acute bronchiolitis is the most important lower respiratory tract infection presenting to paediatricians. It is an acute viral infection of the lower respiratory tract that affects large numbers of infants each winter, being by far the most common single cause of admission to hospital in this age group. It is usually, but by no means invariably, associated with infection by the respiratory syncytial virus (RSV), which can be identified in lower respiratory tract secretions by rapid immunofluorescent techniques. The infection usually begins in the upper respiratory tract, nasal obstruction frequently resulting in feeding problems. Over the next day or two, cough, wheeze and dyspnoea become progressively more severe. On examination, the findings include tachypnoea, inspiratory chest wall recession, evidence of hyperexpansion, and various combinations of fine and coarse crackles with wheezes. The illness runs a variable course, although most patients admitted to hospital require nasal suction, oxygen and nasogastric tube feeding. A few run a more severe course and require ventilatory support. The use of nebulized ribavirin in the management of these infants remains controversial [33]. However, there are hopes that an effective vaccine against RSV will be available soon, although paediatricians with long memories will recall that previous attempts to develop a vaccine were bedevilled by the development of vaccine-enhanced illness, reflecting the complex immunology of the disease.

It is unclear why some children develop bronchiolitis in response to RSV infection, while others develop nothing worse than a bad cold. A number of environmental factors have been implicated, particularly maternal smoking [34–36]. Although the evidence of a clinical association between bronchiolitis and atopy is conflicting, bronchiolitis is associated with increased numbers of airway mast cells [37] and the immunological response to RSV includes the production of IgE antibodies [38], which in turn is related to the frequency of subsequent wheeze.

Following the acute infection, there is considerable respiratory morbidity over the next few years, at least half the affected infants going on to develop recurrent wheeze. In many children these symptoms are transient and have disappeared by school age, but in others they persist into later childhood [36]. It is notable that most follow-up studies of infants who have had bronchiolitis have shown

that abnormalities of pulmonary function are much more common than symptomatic disability, so that yet a further group of children are entering adult life with reduced respiratory reserve, predisposed to chronic obstructive pulmonary disease in later life [39]. Bronchitis and pneumonia in early childhood have also been associated with chronic obstructive pulmonary disease in late adult life [40]; it is likely that many of these individuals actually suffered from bronchiolitis that had not been identified as a separate disorder during their infancy.

The most common chronic respiratory disease in childhood is asthma, the prevalence of which appears to be increasing for reasons that are unclear. In common with other atopic disorders, asthma has a strong genetic component [41]. A recent twin study from Norway suggested that about 75% of the variation in the liability to asthma was genetic, the remaining 25% being accounted for by environmental influences not shared by the twins [42]; given the extent to which twins normally share identical environments, these influences must indeed be subtle. Postulated environmental influences include maternal smoking (as discussed above), low birthweight, low maternal age [43], early exposure to allergens (including exposure *in utero*), exposure to viral infection [37], lack of exposure to infection, excessive vaccination, lack of bacille Calmette–Guérin (BCG) vaccination and reduced antioxidant reserves [44].

Although atmospheric pollution is popularly believed to be responsible for the recent increase in the prevalence of asthma, studies in children living in the Highlands of Scotland [45] have shown a high prevalence of wheeze and asthma in a notably unpolluted area, studies in the

north of England have shown no difference between the prevalence of respiratory symptoms between young men living in urban and rural areas [46], and studies in Surrey actually showed a significantly lower prevalence of asthma-like symptoms in children living near motorways [47].

Nevertheless, whatever the reason, it does appear that the prevalence of childhood asthma has increased [48] and is continuing to increase [49]; in a recent review, Sears [50] states that of more than 20 sequential studies, none has shown a decrease in asthma prevalence with time. Clearly the genetic constitution of the population has not changed in a single generation, and environmental influences must be responsible. The increase in asthma-like symptoms has been accompanied by a similar increase in eczema and hay fever [48,49], whereas the prevalence of wheeze triggered only by upper respiratory tract infection has remained relatively static at around 7%. Wheeze is roughly twice as common following atopy-related asthma in childhood as following infection-related wheeze [51,52] so unless a correctable cause is found for the increase in childhood asthma, adult respiratory physicians can anticipate a continuing increase in asthma-related activity over the coming decades. Based on data from the papers cited above, it can be estimated that we are on course for an adult asthma prevalence of 25%.

This brief review has tried to demonstrate that the prognosis and prevalence of many childhood respiratory diseases are changing, and that these changes are likely to be translated into important changes in the spectrum of disease seen in adult respiratory practice. As far as chest disease is concerned, the child is truly father of the man.

# DIVING AND THE LUNG

STEPHEN J. WATT

The term 'diving' refers to activities carried out underwater that necessitate either a breath-hold or the use of breathing apparatus. It includes recreational snorkelling and scuba diving, deep breath-hold record attempts and a range of commercial activities using various types of breathing apparatus. It also includes specialized techniques such as closed-circuit breathing apparatus with oxygen for covert military operations and deep commercial diving using saturation techniques and the use of helium or other alternative inert gases. All these activities have important implications for respiratory physiology and pathology. What makes the underwater environment dramatically different from other toxic environments is the density of water and its impact on the ambient environmental pressure.

The lung is of critical importance in diving for several reasons. Apart from the necessity to maintain adequate gas exchange, the lung is the largest gas-containing space in the body and hence plays an important role in the maintenance of buoyancy. At the same time there is a risk of rupture due to overpressurization, which may lead to fatal consequences such as tension pneumothorax or air embolism. Furthermore, the lung has a crucial role in protecting the body from the pathological effects of gas bubbles formed during the ascent phase or decompression from a dive. Without this benefit, activities underwater would be much more restricted by decompression sickness.

This chapter describes the major effects of the underwater environment on lung physiology, potential pathological outcomes and the importance of assessment of lung function in determining an individual's fitness to dive.

## Physics and physiology

### Diving physics

On land at sea level, humans are exposed to an ambient pressure of 100 kPa (760 mmHg), this pressure resulting

from the mass of gas in the earth's atmosphere above sea level. Since gas is compressible, as altitude increases the pressure falls in a non-linear relationship with height. However, water is effectively non-compressible and is much denser than air. Therefore, underwater the pressure increases rapidly and linearly with depth; for every 10 m of seawater (msw) depth the pressure increases by 100 kPa. This substantial pressure change has important implications.

The gas laws are particularly important to the understanding of diving physiology. Boyle's law states that for a given mass of gas, the volume is proportional to the absolute pressure. Thus a balloon holding 10 L of air at sea level (100 kPa) reduces in volume to 5 L on descent to 10 msw (200 kPa) and to 1 L at 90 msw (1000 kPa). This is of direct relevance to the breath-hold diver who may take a large inspiration to total lung capacity (TLC) on the surface but at only 10 msw finds the lung volume close to functional residual capacity (FRC). The world record for breath-hold diving is in excess of 120 msw [1], which takes the diver's intrathoracic gas volume well below normal residual volume (RV). A diver using breathing apparatus underwater maintains relatively normal lung volumes, but a much greater mass of gas is required. The implications of the increase in gas density are described below.

Dalton's law states that in a mixture of gases, the total pressure exerted by the gas mixture is the sum of the partial pressures of each of the constituent gases in the mixture. Hence in air at 100 kPa, the pressure results from a  $P_{N_2}$  of 79 kPa, a  $P_{O_2}$  of 20.9 kPa plus small contributions from carbon dioxide and noble gases. If air is breathed at 10 msw, where the total pressure is 200 kPa, the resultant partial pressures are doubled, i.e. a  $P_{N_2}$  of 158 kPa and a  $P_{O_2}$  of 41.8 kPa. While gas concentrations are frequently used in medicine, the body's physiological response is to partial pressure; thus breathing air at 10 msw produces the same oxygen tension and physiological effect as breathing 40% oxygen at sea level.

Henry's law deals with the solution of gases and states

that the amount of gas dissolving in a fluid depends upon the partial pressure of the gas to which the fluid is exposed. This means that as the partial pressure increases, the amount of gas that can dissolve in body tissues increases. At sea level the average human has the equivalent of 1 L of nitrogen dissolved in body tissues. At 10 msw, after adequate time for complete equilibration, double that mass of gas has dissolved. This additional gas dissolved in tissues while the diver is exposed to increased pressure must come out of solution on or after return to the surface and is the source of the gas bubbles that cause decompression illness.

### Immersion

Immersion in water has a number of important consequences for the lung. The pressure differential from the feet to the chest when standing upright is almost 1.5 m of water. This is sufficient to have important circulatory effects. The additional hydrostatic pressure on the dependent limbs tends to force blood from the legs up into the chest. This has been measured and amounts to about 700 mL additional intrathoracic blood volume within the large vessels and the pulmonary circulation [2]. The increase in intrathoracic blood volume has secondary effects. Right heart pressures rise [2] and may result in a diuresis and hence a loss of total plasma volume [3]. The increase of blood volume in the pulmonary capillary vasculature may affect ventilation-perfusion balance mechanisms [3,4]. However, the most striking impact is a direct mechanical reduction in lung volumes, with a reduction in vital capacity (VC) of about 300 mL [5] that results mainly from the blood volume shift [2], though direct hydrostatic compression contributes. These measurements have been made in subjects standing erect in water with the head above the surface and are made after a period of stabilization [3,6]. In diving, posture is variable and so the available VC may change. The additional blood within the pulmonary circulation also appears to increase closing volume [7] and reduce flow rates at low lung volume [6]; hence it is associated with earlier closure of airways on expiration. This may be of considerable importance during rapid ascent as a possible cause of gas trapping [5,7].

The large pressure differential across the height of the body also imposes problems associated with the work of breathing. Normally, in the absence of airflow, there is no significant pressure differential between the mouth and the alveolar spaces of the lung. When submerged, there may be 30 cmH<sub>2</sub>O pressure differential between the mouth and the centre of the lung in the erect posture. This results in an additional workload to be overcome in order to inhale gas and imposes a further limitation on VC. The pressure differential is reduced when the diver is in a horizontal position and reversed when head down. In

practice divers usually find that a slight head-down posture is most comfortable during heavy exertion (finning). This reduces the workload of inspiration but imposes a small expiratory resistance.

### Breath-hold diving

Although breath-hold diving represents the simplest form of underwater activity, it generates some interesting physiological consequences. The breath-hold diver encounters all the problems of pressure change, immersion and buoyancy; in addition, gas exchange during a breath-hold dive is complex [8]. As the diver descends commencing with the lung at TLC, all the alveolar gas tensions rise in proportion to the increase in ambient pressure. Thus at 10 msw both alveolar  $PO_2$  and  $PCO_2$  have doubled. At depth,  $PO_2$  falls with consumption, while  $PCO_2$  is altered by production and solution. On ascent all gas tensions fall. If the alveolar  $PCO_2$  has been reduced by hyperventilation before the dive, there is a delay in stimulation of ventilation by carbon dioxide and no hypoxic stimulus as a result of the elevated  $PO_2$ . In this circumstance,  $PO_2$  may reduce sufficiently on ascent to result in an acute hypoxic episode known as shallow water blackout.

Although the importance of the diving reflex is uncertain in humans, it can readily be demonstrated and results in a significant bradycardia [9,10] and disturbance of left ventricular function [11]. At the same time, the efficiency of gas exchange is influenced by alterations in the distribution of pulmonary blood flow [12].

### Breathing apparatus

Diving means using underwater breathing apparatus. Although very good, most breathing apparatus systems produce an impact on ventilation. This is because there is an inevitable dead space, and a resistance to breathing during both inspiration (mainly until the demand valve opens) and expiration (breathing out through the exhaust valve). Though small, the combined effect of resistance and dead space causes a significant increase in the work of breathing associated with any given workload [13]. These effects are in addition to the reduction in VC and increase in the work of breathing associated with immersion.

The effect of immersion and breathing apparatus is well demonstrated in a study by Dressendorfer and colleagues [14] in which volunteers exercised in air and immersed in water to the neck with and without breathing apparatus. For similar levels of workload (oxygen consumption), minute ventilation was reduced from a control value of 146 L/min to 130 L/min when immersed and to 108 L/min when immersed and using breathing apparatus. A degree of carbon dioxide retention is inevitable.

## Gas density

With increasing pressure the diver's air or breathing gas becomes more dense. This imposes significant limitations on ventilation [15] that can be assessed by measurement of maximum voluntary ventilation (MVV). At 100 kPa, MVV is approximately 180–200 L/min. When breathing air, the effect of gas density is readily detected at quite shallow depths, for example at 30 msw (400 kPa) MVV is reduced to 100 L/min and at 50 msw (600 kPa) to 65 L/min [15,16]. On the surface, MVV is only sustainable for 20–30 s and the maximum sustainable ventilation over a period of several minutes is 70–80% MVV [17].

Underwater, for the same workload (oxygen consumption and carbon dioxide production) approximately the same minute ventilation is required to maintain a similar alveolar  $P_{CO_2}$ . Lung volume remains relatively unchanged. The mass of carbon dioxide produced remains the same, although it occupies a smaller volume within the alveoli. As a result the alveolar concentration of carbon dioxide is reduced but the partial pressure exerted is unchanged. The net effect of this is that if high levels of exertion are achieved underwater, it may be physiologically impossible to maintain adequate alveolar ventilation and carbon dioxide retention occurs. This is a well-recognized cause of loss of consciousness underwater. Various studies have demonstrated that divers tend to retain carbon dioxide [18–20] and that carbon dioxide retention underwater may reach dangerous levels without the diver recognizing the problem [21].

## Decompression illness

### Pulmonary barotrauma

Barotrauma is the term given to tissue damage that results from a change in pressure within a gas-containing space in or around the body. It can therefore affect the middle ear, sinuses, bowel, spaces between the body and the mask or suit and the lung. Pulmonary barotrauma is potentially the most serious pressure-related illness because of the severity of the outcome of arterial gas embolism.

Barotrauma may affect the lung in two ways. The lung may be compressed due to a rise in ambient pressure when the diver cannot breathe in (lung squeeze). This may occur either during a deep breath-hold dive or where breathing gas supply is lost during a rapid descent. The first scenario has been described above. The breath-hold diver takes a large breath, closes the glottis and descends. As pressure rises, the lung volume decreases. Around or below RV, there is increasing likelihood that the thorax and lung tissue are not adequately compliant to reduce in volume and hence the relative vacuum in the alveoli leads to rupture of alveolar walls and results in alveolar exudate and haemorrhage [22]. During the subsequent ascent, gas

within the lung re-expands and the diver surfaces with symptoms of cough, haemoptysis and sometimes breathlessness [20]; disturbance of blood gas tensions may result from the alveolar haemorrhage.

This event is rare in circumstances where the diver has a breathing gas unless there is a failure of gas supply. In the absence of a non-return valve, a surface supplied diver's lungs are effectively compressed by the hydrostatic pressure. Alternatively it may affect a scuba diver attempting to descend quickly. To do this he or she maintains a low lung volume in order to reduce buoyancy. If at this point the diver is unable to breathe in due to loss of gas supply, there is increasing loss of buoyancy and acceleration downwards with progressive reduction of lung volume.

Barotrauma of the lung on ascent (burst lung) is of much greater importance both numerically and in terms of morbidity and mortality. It occurs when the diver is breathing compressed gas underwater. The diver breathes with normal lung volumes at depth. On ascent the volume of gas in the chest expands and the diver must therefore breathe out to enable the expanding gas to escape. During a controlled ascent this is achieved by breathing normally. During a rapid ascent the diver may need to breathe out continuously or at least keep the mouth and glottis open. If the expanding gas is unable to escape from the lung, the transpulmonary pressure increases and the lung may rupture. It seems that rupture most likely occurs at alveolar level and that gas then expands and spreads throughout the interstitial tissues of the lung. This may result in alveolar haemorrhage [23]. The gas makes its way following the line of least resistance to the hilum [24] and from there may spread up into the mediastinum (Fig. 57.1), down into the retroperitoneal space [25,26] or through the parietal pleura into the pleural space (Fig. 57.2). Alternatively, gas may rupture through the visceral pleura into the pleural space. Finally, the tissue damage within the lung may allow the gas access to the pulmonary venous system and expanding gas then passes to the left heart and into the systemic circulation resulting in severe neurological injury or death [27].

Theoretically, any pathological lesion that interferes with gas escaping from the lungs in an evenly distributed fashion may result in shear stress forces between parts of the lung and lead to rupture. In addition, a lung that has previously ruptured spontaneously is likely to be at increased risk. Lesions which might do this are localized bullae, areas of fibrosis or scarring or major obstructions to the bronchial tree. The importance of generalized airflow limitation is difficult to assess. On normal expiration the airways tend to close and trap gas in the alveolar space. However, on ascent, gas escape is only partly by normal expiration because expanding gas tends to splint the airways open and hence vents itself. Forceful attempts to expire might themselves be harmful by prevention of gas

**Fig. 57.1** (a,b) Two chest radiographs of a diver taken during decompression in a chamber after pulmonary barotrauma showing pneumomediastinum. Expansion of the mediastinal gas resulted in prolonged decompression.

**Fig. 57.2** Chest radiograph of a diver following pulmonary barotrauma of ascent showing extensive peripheral shadowing. Diver surfaced with tension pneumothorax.

escape because of airway closure. Such airway closure occurs at an earlier phase of expiration than normal because of the additional fluid in the pulmonary circulation.

A recent study of submarine escape trainees has demonstrated that the risk of pulmonary barotrauma appears to relate better to the lung volume, i.e. forced vital capacity (FVC), than to forced expiratory volume in 1 s ( $FEV_1$ ), though the association is weak [28]. This is a logical finding and is consistent with the other medical evidence available. In the water, VC is restricted by fluid shift to the lung but tidal volume remains unchanged. Inspiratory reserve volume (IRV) is, therefore, reduced. If during normal tidal breathing, a diver commences ascent but fails to breathe out, IRV represents the volume by which the lung can expand before reaching normal maximal volume. Hence if IRV is small as it may be in a diver with a low VC, the lung may be at greater risk of rupture.

In most cases pulmonary barotrauma occurs as a result of an uncontrolled ascent. Two common scenarios are recognized. Exhaustion of the scuba diver's compressed gas supply leaves the diver struggling to obtain a last breath of air from the empty cylinder. The diver has to make a potentially strenuous ascent and, despite knowing that there is no further breathing gas available, must remember to breathe out continuously. Although considerable effort is placed on diver training to cope with this event, it is difficult to breathe out adequately and it remains a high-risk

situation. An alternative but increasingly common scenario is loss of buoyancy control. As the diver commences ascent, air within the diver's dry suit or buoyancy compensator expands and provides increased buoyancy and an accelerating ascent. This gas must be dumped (exhausted from the suit) through valves in order to maintain neutral buoyancy and control. Valve failure or inversion into the feet-up position may make it impossible to dump gas and hence an explosive ascent to the surface with a grossly overinflated suit occurs.

As gas expands within the lungs and is unable to escape, the transpulmonary pressure increases and the lung may rupture when the pressure exceeds 60 cmH<sub>2</sub>O [29]. It appears that it is distension of the lung rather than simply the pressure that is important, since in animal experiments the transpulmonary pressure that can be tolerated can be substantially increased by supporting the chest with binders [29]. In the diver a certain amount of chest movement restriction may be imposed by suit and harness. Nevertheless, pulmonary barotrauma has been reported after dives from very shallow depths of less than 2 msw and has also been reported after breath-hold dives [30,31].

Pulmonary barotrauma should be suspected whenever respiratory symptoms occur after a dive, particularly if there is a history of rapid or uncontrolled ascent. In most cases the presentation is immediately after the dive but delay in onset of symptoms is reported [32] and may be common when pneumomediastinum is the only manifestation. Pneumothorax may present with typical symptoms following surfacing from a dive. However, if the lung ruptures during the ascent phase of the dive more than a few metres from the surface and produces pneumothorax, the continued expansion of the gas within the pleural cavity results in tension that may have fatal results. The symptoms and signs of pneumothorax are no different from pneumothorax in any other situation and treatment is also the same, with one exception. If pneumothorax occurs to a diver who is in, or retrieved to, a closed diving bell or decompression chamber, the opportunity exists to relieve symptoms by compression. This results in reduction of the volume of the gas in the pleural space and relief of tension. This offers an emergency therapy or means of controlling symptoms while arrangements for pleural drainage are made.

Pneumomediastinum usually results in central chest discomfort, hoarse voice and sometimes breathlessness. Symptoms are rarely sufficient to require active treatment, but again recompression does offer an emergency treatment if large volumes of mediastinal gas are causing circulatory disturbance. Pneumomediastinum has caused considerable difficulty when it has occurred during deep saturation diving, since the gas expands so much during decompression and must be absorbed during this period. The decompression may therefore have to be considerably

prolonged to allow time for gas absorption. Pneumomediastinum may present with some delay after surfacing from a dive with symptoms of neck discomfort and voice change associated with subcutaneous emphysema. Pneumoperitoneum is a relatively rare occurrence but causes diagnostic difficulty since the patient may present with abdominal pain and have radiological evidence of free gas in the peritoneum.

Pneumothorax, pneumomediastinum and pneumoperitoneum are all helped by breathing 100% oxygen since this speeds up the elimination of the inert gas from the gas space [33]. This technique depends on the concentration of oxygen rather than the partial pressure and hence is of very limited application in saturation diving since 100% oxygen can only be given on the surface or at relatively shallow depths (to 18 msw).

Arterial gas embolism usually presents with symptoms very soon after reaching the surface. The diver may give a shriek on arrival at the surface, probably due to the release of gas under pressure from the chest. It seems possible that it is at this time, when the intrathoracic pressure falls, that gas is best able to pass through the pulmonary venous system. Thus in at least some cases the arrival of gas in the cerebral circulation probably occurs within seconds of arrival on the surface. The presentation is with acute onset of major cerebral disturbance, loss of consciousness, blindness, hemiplegia, convulsion, etc. [27,34]. Sudden death may result from embolization of the coronary circulation. The natural history of this condition is variable, some patients making a rapid and complete recovery without treatment, others having permanent neurological injury despite rapid treatment [19,27]. Recompression rapidly reduces the volume of gas within the circulation and if achieved at an early stage may produce complete resolution of all symptoms [27]. Recompression is usually followed by hyperbaric oxygen treatment [35], which has three aims: (i) it reduces the inert gas load within the vascular space and other tissues, (ii) it may provide oxygenation to tissues that remain hypoxic as a result of the injury and (iii) it may help to prevent reperfusion injury in those tissues which had lost their blood supply.

Because of the severity of the outcome of pulmonary barotrauma, considerable efforts are made to prevent its occurrence. These efforts follow two avenues. The most important depends upon diver training, primarily to ensure that the circumstances leading to an emergency or uncontrolled ascent do not occur and, secondarily, to reduce the risks should an emergency ascent become essential. Considerable argument exists about whether practical emergency ascent training causes more harm than it prevents [36]. The second area is to identify individuals who may be at increased risk of pulmonary barotrauma. This is considered to be a crucial component of a diver's medical assessment for fitness. A variety of conditions have been considered potential risk factors, includ-

ing the presence of lung bullae or cysts [37], previous spontaneous pneumothorax, localized airways obstruction and generalized airways obstruction [38]. Theoretically any condition that impairs lung compliance may also represent a risk, particularly if this is patchy since this may result in shear stress within the lung as it expands. Impairment of lung compliance has been demonstrated in a number of survivors of pulmonary barotrauma [39] but it is not clear whether this represents a pre-existing risk factor or a result of the injury.

Barotrauma may also occur to the thorax rather than to the lung. A number of incidents have occurred where a diver has experienced an uncontrolled ascent that has resulted in overpressurization of the lung but without any evidence of its rupture. Nevertheless, these divers have suffered from considerable and prolonged chest discomfort which appears to arise from the chest wall. In some the symptoms settle over a few months but in others the discomfort has persisted for years.

Mild degrees of pulmonary overpressurization occurring on ascent but insufficient to cause barotrauma may result in restriction of venous return to the heart and syncope [40].

### **Decompression sickness (the lung as a bubble filter)**

The lung, or rather the pulmonary circulation, plays a critical role in the prevention of decompression illness. Decompression illness results from the formation of gas bubbles within body tissues from inert gas previously dissolved in tissues. As the ambient pressure falls, tissues become supersaturated with inert gas that may then come out of solution. Gas in tissues results in limb pain (the bends), constitutional symptoms of fatigue and malaise and diverse neurological manifestations. More severe episodes may cause respiratory symptoms, circulatory collapse and even death. Bubbles form in many tissues but a considerable proportion find their way into peripheral capillaries and travel through the venous circulation to the lung [41–43]. A gas bubble acts as a foreign surface, thus provoking a response from the coagulation system and being rapidly transformed into a small protein–platelet embolus with a gas nucleus [44]. These microbubbles pass into the pulmonary circulation and are trapped within the pulmonary capillary bed [45]. The quantity of gas bubbles formed during or after a decompression can be monitored using ultrasound imaging or Doppler techniques [46,47]. Neurological manifestations of decompression illness appear to be associated with the appearance of bubbles within the arterial circulation [47]. Bubbles may gain access to the arterial circulation in the presence of a right-to-left cardiac shunt, for example atrial septal defect [48] or patent foramen ovale [49,50], in the presence of intra-

pulmonary shunting or when the volume of bubbles is sufficient to cause a rise in pulmonary arterial pressure above a threshold, as has been demonstrated in an animal model [51,52]. There is growing evidence that pulmonary abnormalities that may be associated with a disturbance of pulmonary circulation are risk factors for neurological decompression illness [53].

Pulmonary decompression sickness presents with severe symptoms of chest tightness, breathlessness and cough and is due to massive bubble embolization of the pulmonary capillary bed, usually as result of severe decompression stress (omitted decompression). Fortunately, such presentations are rare but are often fatal and almost inevitably associated with severe neurological manifestations. However, mild respiratory symptoms of transient chest tightness and cough are commonly reported in divers shortly before the onset of neurological symptoms and may represent a lesser degree of pulmonary bubble embolization.

Obstructive airways disease has been identified as an independent risk factor [53] and there are anecdotal case reports of decompression sickness in association with unilateral absent pulmonary artery [50].

The process of bubble capture within the pulmonary capillary bed is also a cause of concern with regard to possible long-term effects. A fall in diffusing capacity (*DLCO*) occurs after deep saturation dives [54], where the potential for bubble formation is present over several days, but has also been reported after short air dives to 50 msw [55].

## **Other diving-related pulmonary illness**

### **Oxygen toxicity**

While oxygen is essential for life, it is unfortunately also toxic when breathed at increased pressure. Oxygen causes two major varieties of acute toxic effect. At partial pressures above about 130 kPa, neurological effects may occur that can include muscular twitching, jerks and convulsions. The risks increase with partial pressure and are also increased with exertion and carbon dioxide retention. Hence partial pressures of up to 300 kPa may be used therapeutically with a resting patient but pressures above 150 kPa are a significant risk to a diver in the water. A convulsion may have a fatal outcome for a diver using a simple scuba demand valve held in the mouth by the teeth, and hence a band mask or helmet that enables the diver to use an oronasal mask is a crucial safety precaution when oxygen-enriched breathing mixtures are used. Divers who use oxygen-enriched breathing gas mixtures to obtain a decompression advantage are at risk of cerebral oxygen toxicity [53].

Oxygen also exerts a direct toxic effect on the lung.

Minor abnormalities of lung function have been demonstrated after breathing oxygen at partial pressures of less than 50 kPa [56] and animal experiments have demonstrated histological abnormalities after exposure to oxygen at partial pressures of 60 kPa [57]. In practice, divers tolerate partial pressures of up to 50 kPa for prolonged periods without any obvious symptoms [58]. Above a partial pressure of 50 kPa the onset of symptoms is dose dependent in terms of both partial pressure and duration [59,60]. Acute symptoms of chest soreness on inspiration and cough may occur after 2–3 h at 300 kPa or after longer exposure at lower partial pressure [61]. If exposure is continued, the symptoms progress to include severe discomfort on inspiration, breathlessness and ultimately pulmonary oedema and respiratory failure with the development of diffuse alveolar damage. There have been a number of attempts to characterize the physiological abnormality. The earliest abnormality on investigation is a reduction of VC [61], although it is not clear whether this is a direct result of early development of oedema or simply a result of discomfort on inspiration. At a later stage a more obvious restrictive defect develops and is associated with impairment of diffusing capacity ( $DL_{CO}$ ) [61]. This is a reversible effect and symptoms usually subside over a period of 24–48 h after the end of exposure. The mechanism of oxygen toxicity appears to be the result of local tissue  $PO_2$  increasing the concentration of oxygen free radicals and overcoming the body's normal defence mechanisms. This results in a primary endothelial lesion [62,63]. Evidence for the vascular nature of the lesion is supported by animal studies demonstrating abnormal endothelial cell biochemistry [64–66] as well as by human studies [67,68].

In practice, the development of pulmonary oxygen toxicity presents a problem in the management of decompression illness where divers are treated with quite prolonged periods of hyperbaric oxygenation. This is particularly true when the provocative dive involved the use of oxygen during the decompression or when treatment needs to be repeated. However, tolerance to oxygen can be increased by brief interruptions to the exposure [69,70] and hence most treatment regimens [58] use intermittent oxygen rather than continuous treatment. The use of relatively hyperoxic breathing gas mixtures during saturation diving has also raised concerns about possible long-term effects [71]. It has been standard practice during saturation diving for the breathing gas in chambers to be maintained with a partial pressure of oxygen of about 40 kPa [58]. While divers are working in the water this is increased to about 80 kPa and in the decompression phase to about 50 kPa. Hence divers may be exposed to partial pressures above 40 kPa for periods of up to a month at a time. Small decrements in diffusing capacity ( $DL_{CO}$ ) have been observed after deep saturation dives [54,72] and there is

some evidence to suggest that oxygen exposure may be at least partially responsible [73].

### Near drowning

Many emergency situations in diving may lead to inhalation of water and partial or near drowning. Lesser degrees of water inhalation are probably very common due to leaky demand valves and may be the cause for the so-called saltwater aspiration syndrome [74]. It appears that humans who drown may inhale only very small quantities of water [75]; animal models have shown that very small amounts of inhaled water produce substantial disturbance of lung function, with reduction in lung volume and fall in both compliance and  $SaO_2$  [76]. Hence patients who have suffered a near-drowning incident are inevitably hypoxaemic with a substantial shunt [77]. Clinical examination may reveal little or no abnormality. A chest radiograph may also be normal but may show the development of diffuse alveolar damage (adult respiratory distress syndrome) during the first 12–24 h (Figs 57.3 & 57.4). Hence such patients should always be assessed in hospital and remain under observation during the first 24 h. Management is supportive and may require administration of oxygen, ventilation, antibiotic therapy for secondary infection and other intensive care support. Most patients recover fully, although complete recovery of lung function may take months. A few patients show evidence of permanent lung injury [78] but of more significance is the substantial proportion who survive with permanent neurological injury following the period of hypoxaemia [79].

Most near-drowning accidents in divers occur when the diver is on or close to the surface. However, inhalation of water can occur as a result of various situations at depth, including buddy breathing exercises, failure of demand valve or exhaustion of gas supply. In these situations the immediate effect of water inhalation is partially masked by the increased partial pressure of oxygen in the breathing gas. For example, at 20 msw the diver breathing air has a partial pressure of oxygen equivalent to breathing 60% oxygen on the surface. This may be sufficient to maintain a normal  $SaO_2$ . However, the exertion required to ascend, while at the same time the partial pressure of oxygen in the alveoli is falling, may result in loss of consciousness on arrival at the surface due to acute hypoxia [80,81].

Many diving fatalities are recorded as drowning and while this may be the final pathological insult, other events may have led to incapacitation in the water. The postmortem examination of divers is complex since the presence of gas in tissues may be of considerable importance. Radiological examination [82] and other specialized techniques may be valuable [83,84].

**Fig. 57.3** Chest radiograph of a diver after a near-drowning incident showing bilateral lower zone interstitial shadowing. Diver recovered with administration of supplementary oxygen only.

**Fig. 57.4** Chest radiograph of a diver following a severe near-drowning incident showing widespread interstitial shadowing. Diver developed adult respiratory distress syndrome and was left with permanent impairment of lung function.

## Trauma

Commercial divers are exposed to a number of underwater hazards that arise from the use of special tools. The use of oxygen cutting equipment has become widespread. This technique involves production of an electric arc using a welding rod. However, the rod is hollow and oxygen is

fed under pressure through the rod into the arc in order to accelerate the rate at which the metal is burned. A number of major injuries have occurred as a result of this technique in which either oxygen or steam has collected in the pocket in close vicinity to the cut in progress and then exploded. The effects of the underwater blast have included direct chest trauma, pneumothorax and damage to the diver's

helmet resulting in near drowning. Underwater blast may result in extensive tissue injury, particularly where there is a tissue–gas interface such as at the lung surface [85,86] (Fig. 57.5). Characteristically divers sustaining this injury suffer considerable widespread chest pain suggestive of multiple rib fractures. The management is largely dictated by the depth of the incident and whether the diver is recovered to the surface or to a diving bell and pressure chamber.

Although diving illness and environmental problems have been the major contributors to diving fatalities in the past [87], these problems have become progressively better controlled and trauma is becoming increasingly important as a cause of both morbidity [88] and mortality.

### Hypoxia

In most circumstances the diver breathes a gas that has a partial pressure of oxygen higher than that in air on the surface. However, hypoxia may occur in a number of specific circumstances. The diver may be supplied with a breathing gas mixture containing too little or no oxygen. For example a mixture containing only 2% oxygen provides an adequate partial pressure at 100msw but results in severe hypoxaemia at 10 or 20msw. The breathing gas

**Fig. 57.5** Chest radiograph of a diver taken in a saturation chamber following an underwater explosion showing a pneumothorax on the right and extensive peripheral shadowing more marked on the left.

may be contaminated, for example the intake for an air compressor may include exhaust gas from the compressor's petrol engine resulting in carbon monoxide toxicity. The diver may lose breathing gas supply, and during the exertion of returning to the surface oxygen consumption may exceed the total available in the lung [80,81].

Rebreathing apparatus, which is extensively used for covert operations, also carries a risk of hypoxaemia. This is essentially a closed-circuit breathing system dependent on absorption of carbon dioxide and an adequate supply of oxygen. The supply of oxygen to the circuit needs to be adequate to meet the oxygen consumption of a diver, which may be high when the diver is shallow and not impeded by gas density, yet controlled such that at deeper depths when the diver is resting the oxygen partial pressure does not reach potentially toxic levels. These requirements demand complex equipment and training of the divers.

### Cold gas

Diver's breathing gas is always cold since, with the exception of closed-circuit apparatus, it is almost inevitably supplied from a compressed gas source. The implications of breathing cold dry gas may be important for individuals with cold-induced wheeze. There are also considerable difficulties when helium is used as the inert gas because of its thermal characteristics. Helium has very high thermal conductivity and as a result respiratory heat loss is greatly increased, since the breathing gas acts as a heat conductor from the body core [89]. As the depth and gas density increases, the heat capacity of the breathing gas increases to the extent that respiratory heat loss exceeds the body's total heat production and hypothermia becomes inevitable unless the breathing gas is heated. In practice, this becomes essential below depths of 180msw. Attempting to breathe cold helium–oxygen mixtures at great depth is difficult to tolerate and induces bronchorrhoea.

Cold exposure also has a significant impact on the circulation, with peripheral vasoconstriction, shift of fluid volume to the core and a resulting increase in pulmonary blood volume and rise in right heart pressures [90]. These effects are additive to those of immersion and may contribute to the phenomenon of immersion-induced pulmonary oedema [91], a condition that appears to be more likely in individuals with established or labile hypertension.

### Long-term effects of diving on the lung

Considerable concern exists about the possibility that diving may have some adverse effect on the lung. There is no doubt that divers have larger lung volumes than standard reference populations [92–95]. This may be partly the

result of selection but there is evidence from submarine escape tank instructors that a significant increase in lung volume can occur during a term of duty [96], presumably as a result of repetitive breath-hold diving acting as respiratory muscle training. However, in populations of commercial and military divers a consistent finding is a greater increase in FVC than FEV<sub>1</sub> [94,97]. Further investigation of the resulting reduction in the FEV<sub>1</sub>/FVC ratio has indicated reduced flow at low lung volumes, which may represent a pathological injury to small airways [98–100]. Few longitudinal studies are available but do suggest a reduction in lung volume at a faster rate than anticipated from standard prediction equations [71,101]. These data are difficult to interpret since the change in lung volume during early adult life may not follow a progressive decline even though lung growth may continue until the late twenties [102]. If correct, a more rapid decline than predicted equations suggest may not be abnormal. After deep saturation dives, small but significant reductions in diffusing capacity (*DLCO*) have been observed [54,93]. In some cases there has not been complete recovery. The two factors that may contribute to this are an effect due to long-term exposure to an elevated partial pressure of oxygen, insufficient to induce acute symptoms [73,103], and an inflammatory response to repetitive delivery of gas bubbles to the pulmonary vasculature during prolonged decompressions. Bubbles certainly result in an acute effect on the pulmonary vascular bed [104–106] and the extent of recovery is unclear. However, this effect would also be anticipated in air divers, who do not appear to be subject to the same effect on lung function [107].

## Assessment of fitness to dive

### Rationale

For the reasons obvious from the foregoing discussion, assessment of pulmonary fitness is of considerable importance to the diver. In the UK, commercial divers must undergo a statutory medical examination on an annual basis according to guidelines issued by the Health and Safety Executive [108]. Similar but less extensive medical examination systems are operated by the sport diving organizations and there is a considerable literature concerning this subject [109,110]. Although it is often argued that recreational diving does not require the same medical standards as commercial diving, the safety issues are the same and in practice the risks associated with recreational diving are often greater. It is more important to consider fitness in relation to the type of diving the individual will undertake.

In the UK, the medical examination of commercial divers must be carried out by a doctor approved by the Health and Safety Executive. Although the medical examination of sport divers may be performed by any doctor,

there is a strong argument for seeking advice from a doctor with appropriate knowledge of diving and the medical issues involved.

The objectives of assessment of fitness are to ensure that the potential diver is not suffering from a pre-existing condition that represents an increased risk to the health of the diver and his/her buddies and to ensure an adequate exercise capacity in order to cope with the physical exertion of diving. These two objectives are closely related since involvement in a rescue of an injured or incapacitated diver may be the most strenuous activity a diver has to undertake. It is important to recognize that all diving activities rely upon the divers providing mutual support in the event of emergency. In recreational diving this is known as the buddy system; in most commercial operations, a standby diver is a legal requirement. The diver's ability to respond to assist another diver forms the most important baseline for standards of fitness in terms of exercise capacity. It is reasonable for any diver to expect that other divers who may be required to assist in an emergency are not inefficient in this respect as a result of poor fitness.

### Medical history

The medical history should be free from symptoms of undue exertional breathlessness, cough, chest pain or other limitations to exercise. A history of significant lung disease that may have resulted in a permanent impairment of lung function or structure should be investigated further. Significant kyphosis or other restriction of thoracic movement, diaphragmatic paralysis, etc. represent contraindications. Previous spontaneous pneumothorax is a contraindication as this indicates the presence of an anatomical defect that has ruptured under normal environmental conditions. Although the risk of recurrence falls with time, such defects are more likely to rupture under conditions of increased transpulmonary pressure and the occurrence of a pneumothorax underwater is likely to be fatal due to the tension associated with increasing pleural gas volume on ascent. Conversely, following an uncomplicated traumatic pneumothorax the individual may be able to return to diving, provided that complete recovery occurs. In this situation it is presumed that the lung was normal initially and that complete recovery can occur. Hence provided that lung function and chest radiography returns to normal, the individual can return to diving; high-resolution CT provides greater confidence of the absence of any structural lesion after such trauma. Thoracic surgery is generally considered to represent a contraindication since there is a high risk of pleural adhesion following thoracotomy. For this reason surgical prevention of recurrent pneumothorax by pleurectomy does not change the situation regarding unfitness to dive.

### Exercise underwater

Unfortunately, there is very little information available that provides an accurate measure of the workload in terms of oxygen consumption associated with a diver rescue. Similarly, the relationship between aerobic performance on the surface and work capacity in the water is uncertain. Exercise tests underwater using fin swimming as the exercise have demonstrated that oxygen consumptions of up to 2.5 mL/kg/min can be achieved [18]. This is substantially less than levels achieved on the surface during treadmill walking, which may reflect the different types of muscles involved and the fact that the diver is weightless.

Despite these limitations some assessment of exercise capacity is valuable. In the absence of contrary evidence, it can be assumed that there is a relationship between performance on the surface and underwater ability. A reasonable fitness standard is to require divers to achieve an aerobic performance level that is not below the 50th percentile for individuals in that age group. However, since exercise tolerance falls with age, it would be prudent to use age 40 as the reference age group for all divers over 40. In practice this standard presents little difficulty for the vast majority of divers both recreational and commercial.

### Lung function

The diver's lung function should be normal or, if there is any impairment, this should not be sufficient to affect the diver's ability to exercise underwater. The diver's lungs should not have any anatomical or physiological abnormality that increases the risk of pulmonary barotrauma and the diver should not have any condition that might impair the function of the lung as a bubble filter.

From considerations of pulmonary physiology during exercise and diving, the symptomatic effect of a significant deviation from normal lung function is likely to be magnified in the underwater environment. Hence anyone with abnormal breathlessness on the surface should be considered unfit to dive. The possible exception to this is asthma where the symptoms and functional abnormality is transient (see below).

### Investigations

A chest radiograph is considered essential before commencing diving and is an absolute requirement for commercial divers, although some sport diving associations permit diving without a previous chest film. The purpose of the chest radiograph is to exclude major anatomical defects such as bullae, areas of fibrosis or scarring that may contribute to air trapping or be associated with impaired compliance and hence represent a risk

factor for lung rupture [37,38]. Small old scars due to previous pulmonary tuberculosis do not appear to represent a risk.

Lung function is usually assessed by simple spirometric indices of FEV<sub>1</sub>, FVC and peak expiratory flow rate or flow-volume loop analysis. The purpose is to exclude individuals with diminished lung volume or evidence of airways obstruction. Airways obstruction and the associated air trapping may represent a risk factor for pulmonary barotrauma, although the evidence to support this theoretical risk is limited. However, given that medical examiners have tended to exclude those with obvious abnormalities from diving, the absence of epidemiological evidence to support a risk is not all that surprising. Fortunately, pulmonary barotrauma is a very rare problem and in most cases there is an obvious dive-related provocative factor. This makes assessment of the risk associated with a pre-existing medical problem very difficult. A recent study of submarine escape trainees has demonstrated that the risk of pulmonary barotrauma appears to relate better to the lung volume, i.e. FVC, than to FEV<sub>1</sub>, although the association is weak [28].

The results of lung function tests should be considered in association with the exercise test result. An individual with poor exercise performance and impaired or marginally reduced lung function resulting in poor exercise tolerance is very likely to have substantial difficulty underwater and is unfit. Conversely, if lung function is good, the individual with poor exercise tolerance should be able to demonstrate an improvement with training. A repeat FEV<sub>1</sub> after an exercise test also provides a simple screen for the presence of exercise-induced wheeze.

### The lung as a bubble filter

This is a more controversial area but one likely to become of much greater importance in the future. It is established that the lung acts as a filter to remove bubbles from the circulation and that appearance of bubbles in the arterial circulation is associated with decompression sickness. The Divers Alert Network (DAN) study [111], which set out to look for an association between asthma and pulmonary barotrauma, found an association with diving incidents but not with barotrauma, suggestive of a possible increased risk of decompression illness. This may be related to intrapulmonary shunting since cardiac shunt is a well-recognized risk factor [48–50]. A study by Wilmshurst and colleagues [53] also provides evidence for a relationship between decompression illness and lung disease.

### Returning to dive after a diving accident

There is little published information about the risk of returning to dive following a diving injury. A critical issue

is whether lung function returns to normality after an episode of pulmonary barotrauma. There is some published evidence of individuals having repeated episodes [20], although not all these cases had objective evidence of lung rupture. Colebatch and colleagues [39] found evidence of impairment of lung compliance in survivors of pulmonary barotrauma but it is unclear whether this abnormality existed before, or resulted from, the incidents. It is generally agreed that a diver who experiences an episode of pulmonary barotrauma during normal diving practice should be regarded as having a pre-existing risk factor and be advised not to dive. The diver in whom pulmonary barotrauma occurs as a result of an explosive ascent may be assumed to have had normal lungs before the incident. Hence if a complete recovery is made with a return to normal lung function and no anatomical abnormality can be demonstrated by high-resolution or spiral CT, a return to diving may be possible.

### Asthma

Asthma represents a special situation because it is increasingly common, a growing number of asthmatic subjects wish to dive and because symptoms are transient. The issue has been extensively considered [112,113]. There is no doubt that some asthmatics can and do dive regularly [114] but they may be at increased risk. The DAN study in the USA found that although there was no over-representation of people with asthma among individuals with episodes of pulmonary barotrauma, there was an over-representation of asthmatics when all categories of diving accident were considered together. This is probably a significant finding since many asthmatic patients have received and taken medical advice not to dive. Similarly in an Australian study of diving fatalities, 9% of cases had a diagnosis of asthma [115]. There are various anecdotal reports of both barotrauma in patients with asthma [116] and acute breathlessness occurring in the water [117]. It seems reasonable that there is an increased risk but it may not apply to all patients with asthma.

Potential problems for the diver with asthma would include impairment of exercise capacity, inability to tolerate breathing apparatus, effect of medication on cardiac function, incapacitation due to an episode of wheezing while underwater (which may be provoked by breathing cold gas), breathing dense gas and the possible increased risk of decompression sickness.

Bronchodilator agents, particularly  $\beta_2$  stimulants, all have a cardiac effect that may result in unexpected interaction with the cardiac stimuli associated with diving such as immersion, cold and the diving reflex. On the other hand, their potential protective effect against episodes in the water is used as an argument to support their regular use before diving by some. The diver should be able to go into the water without significant risk of an episode occurring, and the need or desire to take a dose before a dive suggests that symptom control is inadequate. Other agents used prophylactically, such as salmeterol or formoterol, also indicate more severe symptoms or greater difficulty in control. Theophyllines are a contraindication because of cardiac and gastric side-effects and because (at least in the UK) their use indicates poor control [118]. Intensive bronchodilator therapy and theophylline therapy may represent a risk for decompression illness as a result of intrapulmonary shunt.

At present, some patients with asthma may be certified fit to dive provided that they can meet the following criteria.

- 1 When well they are free of symptoms, with normal lung function and no impairment of exercise capacity.
- 2 They should not dive if they have current symptoms.
- 3 They should not have exercise- or cold-induced symptoms.
- 4 Their asthma should be stable, predictable and well controlled and they should not have a regular need for use of relief bronchodilator.

- 5 Patients whose asthma is well controlled on inhaled steroids may meet these criteria even if they use inhaled bronchodilator regularly before each inhaled steroid.

To establish compliance with these criteria an accurate record of previous health from a general practitioner is essential. Asthmatics should be able to demonstrate normal exercise tolerance and the absence of exercise-induced symptoms. Patients whose asthma is brittle, who have had a recent history of severe episodes or who have a regular requirement for relief inhaler therapy or other additional support therapy should be advised not to dive. Above all, patients with asthma need to be informed of the possible increase in risk for asthmatics who dive and that diving when their asthma is troublesome may substantially increase the risk. They should be aware of how to control these risks by modifying their diving practice. Unfortunately, it is very difficult to predict how a patient with asthma will respond to their first diving experience [117].

# ASSISTED VENTILATION

JOHN M. SHNEERSON

## Principles of ventilation

Mechanical ventilators transfer gas into and out of the lungs with the aim of optimizing oxygen transport and carbon dioxide elimination from the body. To achieve this they have to not only ventilate the lungs but also ensure that the mixing of gases within the lungs is efficient, that ventilation and perfusion are well matched and that the ventilator itself does not impair cardiac output. The ventilator therefore acts as an external pump that supplies energy to supplement or replace the activity of the normal respiratory pump. In addition, the ventilator has to fulfil at least some of the roles of the respiratory control system by determining the pattern of respiration. None of the currently available ventilators approaches the complexity and adaptability of the normal respiratory control system, although the microprocessors of modern ventilators are becoming increasingly sophisticated. There is an increasing number of methods of respiratory support that vary in the degree of assistance they provide and which almost merge with spontaneous respiration.

All the positive-pressure ventilators that are applied to the airway work on the principle that if the pressure in the ventilator exceeds that in the patient's alveoli, gas will enter the lungs. This contrasts with spontaneous and negative-pressure ventilation, in which the alveolar pressure is less than atmospheric pressure during inspiration. Positive-pressure ventilators require a source of pressurized gas to be delivered at a controllable flow or pressure to the patient without dilution with ambient air. The flow of inspired gas is intermittent in true mechanical ventilation but may be continuous in for instance continuous positive airway pressure (CPAP) support. The expired gas is conducted away from the patient without contaminating the inspired gas except in the dead space of the circuit close to the patient. Expiration is usually passive and due to the elastic recoil of the lungs and chest wall, but can be modified in various ways by the ventilator as well as by the patient's effort.

Negative-pressure ventilators differ from positive-

pressure systems in that a subatmospheric pressure is applied intermittently around the chest and abdomen within a rigid and impervious enclosure so that air is drawn in through the mouth and nose. No appliance is required around or inside the airway and a source of pressurized gas is not needed since the energy of the ventilator is applied to the chest wall rather than to the airway. Negative-pressure systems are therefore a method of external ventilation in contrast to internal ventilation as typified by positive-pressure systems using a tracheostomy or endotracheal tube.

## Control of inspiration

There are a number of ways in which inspiration can be influenced by the ventilator controls, the most important of which are discussed below.

### Initiation of inspiration and termination of expiration

This is often called ventilatory triggering or cycling, although the latter term is confusing because it is also used to designate the changeover from inspiration to the start of expiration. Inspiration can be initiated by one or more of the following methods.

#### *Time*

The expiratory time can be preset so that inspiration follows after a predetermined interval or, on some ventilators, the total time for the inspiratory cycle can be set and the inspiratory–expiratory (I/E) ratio fixed.

#### *Pressure*

The development of a negative pressure by the patient's inspiratory effort can be sensed by the ventilator controls and used to trigger the inspiratory phase of the machine. The usual trigger threshold is 0.5–2 cmH<sub>2</sub>O. Lower thresholds may lead to triggering of the ventilator by, for

instance, cardiac impulses, small leaks or non-respiratory movements. Conversely, if the threshold is too high the patient's inspiratory work may be excessive and failure to trigger the ventilator may lead to incoordination between the patient and the ventilator.

### *Flow*

Inspiration can be triggered when the flow generated by the patient increases above a threshold value set by the ventilator. This is used with some pressure-preset ventilators.

### *Volume*

Inspiration can be initiated when a preset volume has been expired.

### **Termination of inspiration and initiation of expiration**

Inspiration can be terminated by time, pressure, flow or volume criteria. In general the termination of inspiration by pressure is unsatisfactory and leads to incoordination between the patient and the ventilator. Flow cycling promotes coordination but is only suitable for pressure-preset ventilators. Time or volume cycling are appropriate for constant-flow generators.

### **Inspiratory pressure and flow waveforms**

#### *Flow generators*

Ventilators that generate a predetermined flow rate and which have a fixed inspiratory time deliver a predictable tidal volume. The inspiratory flow may be constant, a half sine, ramp or a reverse ramp waveform, although there is remarkably little difference between these in most clinical situations. The adequacy of the mixing of inspired gas with air already in the lungs probably depends more on the inspiratory time than on the pattern of flow. The tidal volume is hardly altered by changes in the elastance or resistance of the ventilator circuit or patient, but in the presence of a leak the flow remains unchanged and the volume delivered to the patient falls. The airway pressure is determined by the elastance and resistance of the upper airways, lungs and chest wall and of the ventilator and circuit.

#### *Pressure generators*

This type of ventilator generates a predetermined pressure waveform that is often but not always a square wave. The inspiratory flow rate and tidal volume is determined by the transpulmonary pressure, which in turn is determined by the elastance and resistance of the lungs and the

patient's effort. The transpulmonary pressure is greatest initially when the pleural pressure is least and the inspiratory flow rate then decreases towards zero as the pressures in the airways equilibrate. Pressure generators do not provide a fixed tidal volume since this varies with the elastance and resistance of the patient, ventilator and circuit, although they can compensate for leaks by increasing their flow rate in order to maintain the preset pressure waveform.

### **Inspiratory limitation**

Inspiratory limitation is a technique used to protect the patient against an excessive pressure or volume delivered by the ventilator. The unwanted gases are vented through a relief valve. Protection against high pressure is needed particularly with flow generators when the elastance and resistance are increased, and against increased volume delivery with pressure generators when they are reduced or if the patient's inspiratory effort increases.

### **End-inspiratory pause**

An end-inspiratory pause is the period after the delivery of the inspired gas but before expiration starts. The airway pressure falls to a plateau level which, since there is no airflow, reflects the elastance of the respiratory system and is independent of the airflow resistance. During the pause, air enters alveoli which have prolonged time constants and their recruitment is thought to improve ventilation-perfusion matching, particularly in patients with diffuse lung diseases.

### **Sigh**

A sigh can be mimicked by positive-pressure ventilators by the introduction of a periodic large inspiration. The depth of the mechanical sigh is usually 1.5–2 times the usual tidal volume and the frequency is often between 1 in 60 and 1 in 100 breaths. Sighs can reverse small airway closure and improve ventilation-perfusion matching but are not as effective as positive end-expiratory pressure (PEEP) or other manipulations of the ventilator controls, such as increasing the tidal volume.

### **Inspiratory–expiratory ratio, frequency and inspiratory–expiratory times**

These various indices of ventilation are interrelated and alteration of one influences the others. Shortening the inspiratory time increases the flow rate in volume-preset generators and, particularly if it falls to less than about 1s, the distribution of the inspired gas to the alveoli is impaired. Conversely, a prolonged inspiratory time may be uncomfortable and although it promotes gas mixing it

also increases the mean airway pressure. A reduction in the expiratory time may lead to air trapping and increased end-expiratory pressure (auto-PEEP).

An increase in the respiratory frequency at any fixed I/E ratio reduces both the inspiratory and expiratory time. An I/E ratio of 1:2–2.5 is satisfactory for subjects with normal respiratory mechanics. A lower ratio reduces the mean airway pressure and increases the cardiac output but at the cost of a deterioration in ventilation–perfusion matching. Increasing the I/E ratio has the opposite effect. The extreme is inverse ratio ventilation, where the inspiratory time exceeds the expiratory time. This assists oxygenation through prolonging the inspiratory time and increasing the end-expiratory volume but may significantly reduce cardiac output.

### Control of expiration

The most important methods of influencing expiration include the following.

#### Expiratory retard

This is a method of prolonging expiration by increasing the resistance of the expiration valve, usually by narrowing its diameter. It is equivalent to pursed-lip breathing in emphysema. Like this, it moves the equal pressure point proximally and so reduces air trapping. It differs from PEEP or CPAP in that the resistance does not have a threshold value above which it is brought into action. Expiratory retard has the disadvantage of raising the mean intrathoracic pressure and reducing cardiac output.

#### Negative end-expiratory pressure

Negative end-expiratory pressure can be achieved by entraining air in the expiratory limb of the ventilator circuit by the Venturi effect. This reduces the expiratory pressure and thereby increases the venous return to the right ventricle. However, it may cause narrowing or closure of small airways and distal lung collapse.

#### Positive end-expiratory pressure

PEEP is the maintenance of pressure above atmospheric at the end of expiration but is in practice applied throughout the expiratory phase. The term is restricted to a positive pressure applied during ventilation, in contrast to expiratory positive airway pressure (EPAP) or CPAP, which refer to manipulations during spontaneous breathing. PEEP is maintained by introducing a threshold resistor in the expiratory circuit. It tends to prevent airway closure during expiration with the result that the end-expiratory volume increases. This improves ventilation–perfusion matching

and raises  $P_{ao_2}$ , particularly in restrictive disorders such as diffuse lung fibrosis and neuromuscular diseases [1]. The elastance of the lungs falls unless they become hyperinflated, in which case it increases. The increased lung volume and intrathoracic pressures may also lead to pneumothorax and other pulmonary barotrauma. Cardiac output and venous return are reduced as a result of the increased mean intrathoracic pressure. This may be clinically important especially if the cardiac output is already low, if the blood volume is reduced or if autonomic reflexes are impaired.

### Modes of ventilation

There is a spectrum of respiratory assistance between the extremes of spontaneous independent respiration and completely controlled mechanical ventilation (Figs 58.1 & 58.2). In the centre of this spectrum are the partial ventilatory support techniques which, if they can maintain ventilation adequately, are usually preferable to controlled ventilation since ventilation–perfusion matching is better and respiratory muscle strength and coordination are preserved. Partial support techniques can be adjusted according to the patient's requirements. For instance, the frequency, tidal volume, level of pressure support and method of triggering can all be individually adjusted so that the patient has some degree of control over the respiratory pattern. The nomenclature of the modes of ventilation is complex and inconsistent [2], but in general they are distinguished by the methods by which inspiration is assisted or triggered. The most important techniques are discussed below.

#### Controlled mechanical ventilation

Controlled mechanical ventilation delivers inspired gas at a preselected pressure (pressure controlled) or volume (volume controlled) with a fixed inspiratory and expiratory time. These techniques are suitable if the patient is unable to trigger additional breaths but not when respiratory drive and muscle strength remain. Controlled mechanical ventilation is indicated if the patient is sedated and given muscle paralysing agents, is unconscious, or has no respiratory muscle effort due to complete paralysis of the respiratory muscles as in high cervical tetraplegia.

#### Assist and assist control ventilation

In these techniques a preset tidal volume is delivered by the ventilator with a preselected inspiratory time. The ventilator can be cycled into inspiration by time or this can be triggered by a reduction in pressure caused by the patient's inspiratory effort. However, in assist ventilation a back-up rate provided by time-cycling into inspiration is

**Fig. 58.1** Pressure–time relationships during controlled mechanical ventilation with positive end-expiratory pressure.

**Fig. 58.2** Flow and pressure changes with different modes of ventilation. During controlled mechanical ventilation (CMV), patient effort does not result in airflow in contrast to assist control ventilation (ACV). The flow rate is determined by the patient when using pressure support ventilation (PSV), continuous positive airway pressure (CPAP) and spontaneous breath with intermittent mandatory ventilation (IMV).

absent. The degree of patient effort can be modified by altering the pressure threshold for triggering into inspiration and the back-up rate. Assist control is a safer technique than assist if there is any doubt about the respiratory drive or respiratory muscle strength or endurance.

### **Intermittent mandatory ventilation and synchronized intermittent mandatory ventilation**

In intermittent mandatory ventilation (IMV) and synchronized intermittent mandatory ventilation (SIMV), the ventilator delivers breaths of a preset volume with a preset inspiratory time. Additional spontaneous breaths can be taken through the ventilator, which therefore should have a low resistance and an adequate supply of fresh gas available, usually from a reservoir, between the controlled breaths. In IMV the machine breaths are delivered at regular intervals independent of the timing of the patient's spontaneous breaths, but in SIMV they are synchronized within limits with the patient's spontaneous breaths. This avoids breath stacking, which is common with IMV. The patient's work of breathing can be regulated by changing the IMV or SIMV rate and by the addition of inspiratory pressure support to the spontaneous breaths. IMV and SIMV therefore provide a combination of assisted and spontaneous inspirations that differ in their pressure and flow characteristics.

### **Inspiratory pressure support ventilation**

With this technique the ventilator delivers an inspiration with a preset pressure waveform that usually results in a decelerating or reversed ramp pattern of airflow (Fig. 58.3). Inspiration is terminated either by a fall in the

flow rate or by time; the expiratory time is determined either by the patient pressure- or flow-triggering the next inspiration or by time. The patient therefore has more control over the respiratory pattern than with the previous modes but a preselected tidal volume is not guaranteed. This depends on the elastance and resistance of the patient's respiratory system and the ventilator circuit, as well as on the patient's inspiratory effort. Pressure support ventilation does not provide a reliable tidal volume if the patient's mechanics change. However, it is able to compensate for air leaks. The ventilator is usually flow-cycled, which gives a shorter response time than with pressure cycling. Pressure support enables the work of breathing to be graduated by altering the applied inspiratory pressure.

### **High-frequency ventilation**

High-frequency ventilation is the term used to describe ventilatory techniques in which the respiratory frequency is greater than 60/min. Air can be delivered using conventional positive-pressure ventilators at a high frequency, with jet ventilators and high-frequency oscillators. Oscillation can be applied directly to the column of gas in the airway or externally to the chest wall. This method can be used without intubation, although mechanical coupling to the patient is often difficult. With each of these techniques both inspiration and expiration are usually active and although the tidal volume is smaller than with conventional frequency ventilation, alveolar ventilation can be maintained. The pressure swings are much less than with conventional techniques and this minimizes the risk of pulmonary barotrauma and the reduction of cardiac output. However, high-frequency ventilation may increase the end-expiratory volume, particularly if the

Fig. 58.3 Bilevel pressure-support ventilator.

expiratory time is excessively reduced. It has not found wide application but can be of value with laryngeal surgery and in the management of bronchopleural fistulae, since the inspired gas is not preferentially directed through the low-impedance fistula as it is in conventional ventilation.

### Other modes

A wide range of other modes of ventilation has been introduced over the last few years, including proportional assist ventilation, mandatory minute ventilation and airway pressure release ventilation. The current indications for these are limited [3].

### Aims of ventilation

Mechanical ventilation is only one component of the overall management of patients with ventilatory failure, and it is important to have clearly defined aims whenever a patient is ventilated. These vary between individuals but the most important are described below.

### Control of arterial blood gases

In general, the  $P_{O_2}$  should be kept between 8 and 12 kPa (60–90 mmHg), at which levels the oxygen saturation is usually over 90%. This may require supplemental oxygen as well as ventilation if the gas-exchange function of the lungs is severely impaired. Wherever possible, the  $P_{CO_2}$  should be brought within the normal range in order to improve the hypercapnic drive and to make withdrawal of ventilatory support easier. Occasionally, patients with very abnormal respiratory mechanics cannot be ventilated without the peak inspiratory pressure rising to levels where barotrauma is a significant risk (40–50 cmH<sub>2</sub>O) and in these situations controlled hypoventilation (permissive hypercapnia) may be the best policy [4,5]. Conversely, hyperventilation to reduce the  $P_{CO_2}$  to around 4 kPa (30 mmHg) is indicated if ventilation is used to reduce intracranial pressure.

### Substitution for a failed or inactivated respiratory pump

In certain circumstances, for example anaesthesia, the patient carries out no respiratory work and the ventilator substitutes for this. The controlled mode in which the patient's tidal volume, respiratory frequency and inspiratory and expiratory times are preset is usually used.

### Supplementation of the patient's respiratory activity

In these circumstances the patient contributes to respira-

tion but the ventilator acts as an additional external energy source. It is important to try to synchronize the patient's and the ventilator's respiratory cycles. For instance, if the patient exhales during an inspiration with a volume-preset ventilator, the pressure limit would be reached early and air vented from the system. Conversely, with a pressure-preset ventilator, synchronization of the patient's inspiration with the ventilator's inspiration increases the tidal volume.

### Modification of the patient's respiratory activity

The ventilator not only provides respiratory support for the patient but also interacts with the patient's respiratory control system and modifies the respiratory pattern. This may occur as a result of an improvement in the blood gases, which alters the biochemical respiratory drive, and also by relieving anxiety and discomfort by providing adequate respiratory support. More complex interaction is also possible involving breath-to-breath and intra-breath reflex changes to the respiratory drive, which are determined by the type of ventilatory support [6].

### Treatment of the underlying condition

Mechanical ventilation can to a limited degree treat as well as support ventilatory failure. Most of its effects are transient, but with long-term nocturnal ventilation some must persist long enough to explain the clinical and physiological improvement seen during the day. The possible mechanisms of these improvements are changes in the following parameters.

#### Respiratory drive

Mechanical ventilation can improve respiratory drive by lowering  $P_{aCO_2}$  and relieving hypoxic depression of the respiratory centres and sleep deprivation. It also has more subtle and dynamic interactions with the patient's respiratory drive through reflexes, as mentioned earlier.

#### Respiratory muscle function

Respiratory muscle fatigue has been postulated as a cause of ventilatory failure and of difficulty in weaning, although this has only been demonstrated in a few circumstances. It is more likely that the respiratory control mechanisms adapt to prevent fatigue developing. Nevertheless, the practice of resting the respiratory muscles, particularly during acute illnesses or when the patient is systemically unwell, is probably advisable in order to avoid near-fatiguing work. In other circumstances, increasing the patient's work of breathing using partial respiratory support techniques may increase respi-

ratory muscle strength and endurance and improve their coordination.

### **Respiratory mechanics**

Ventilation can improve both lung and chest wall compliance though these effects persist for only a short period after ventilation has been discontinued [7].

### **Ventilation–perfusion matching**

Gas exchange in the lungs depends on the degree of matching of ventilation and perfusion, and this is hard to optimize during ventilation. Regional perfusion is affected by factors such as gravitational forces, lung disease, vascular tone and lung volume as well as cardiac output. The increase in intrathoracic pressure with positive-pressure ventilation reduces intrathoracic blood volume, right ventricular inflow and left ventricular outflow. These problems are most marked if the inspiratory pressure is high and the inspiratory time prolonged or if the mean expiratory pressure is raised as with PEEP and CPAP.

The distribution of inspired gas is very heterogeneous in lung disease. Overdistention of alveoli is thought to be the cause of pulmonary barotrauma. This may be manifested as pneumothorax, pneumomediastinum, subcutaneous emphysema, interstitial emphysema or pneumopericardium. These complications appear to be most closely related to the peak inspiratory pressure and the tidal volume.

In general, ventilation–perfusion matching usually improves if the inspiratory time can be prolonged, with or without an end-inspiratory pause to assist equilibration of gases within the alveoli, and if the tidal volume is increased, with or without PEEP or sighs to prevent airway closure.

### **Control of upper airway function**

An impaired cough, swallowing or speech is common in neuromuscular disorders. Airway protection and access to tracheobronchial secretions with a cuffed tracheostomy or endotracheal tube may be as important as ventilatory support. The same considerations apply to patients who are unconscious, for instance after a drug overdose.

### **Complete or partial weaning**

Ventilation is usually only a temporary phase, although occasionally long-term nocturnal non-invasive ventilatory support is required. It is particularly effective in neuromuscular and skeletal disorders but also in selected patients with chronic airflow obstruction [8]. In effect,

these patients are only partially weaned although they may return to an active life during the day.

## **Gas exchange during ventilation**

The main aim of ventilation is to sustain adequate alveolar gas exchange for the patient's metabolic requirements. However, not all the gas leaving the ventilator reaches the alveoli and it has three distinct destinations, as discussed below.

### **Leaks**

The gas leaving the ventilator follows the path of lowest impedance, which may be into the lungs or through leaks in the system. These may occur within the ventilator or its circuit, at the interface with the patient or within the patient. For instance, gas may leak around a cuffed endotracheal or tracheostomy tube or around a face or nasal mask; with the latter, leaks through the mouth are commonly a problem as well. Leaks within the patient may occur through a bronchopleural fistula or by air passing through the cricopharyngeal sphincter into the oesophagus rather than the trachea.

### **Dead space ventilation**

There are two main parts of the dead space: the volume of the ventilator circuit and the anatomical and physiological dead space. The volume within the ventilator and its circuit depends on the length and diameter of the connecting tubing plus the pressure under which the gas enters the circuit. The tubing is distensible and accommodates 2–3 mL of gas for every 1 cmH<sub>2</sub>O inspiratory pressure (the compressible volume). The volume of the interface of the system with the patient, such as a face or nasal mask, also contributes to the dead space. The dead space of a nasotracheal or orotracheal tube is greater than that of a tracheostomy tube, and with a face mask the dead space exceeds that of a nasal mask or mouthpiece.

Within the patient, the anatomical dead space may be partially bypassed by a tracheostomy but not by non-invasive techniques. The physiological dead space usually increases during ventilation, especially if this causes hyperinflation.

### **Alveolar ventilation**

The rest of the inspired gas is distributed to the alveoli according to factors such as the inspiratory time, the inspiratory pressure and flow waveform and the elastance and resistance of the patient's respiratory system. In most lung diseases the mechanical properties of the lungs are heterogeneous and inspired gas is distributed irregularly. An increase in tidal volume or inspired pressure may simply

distend those alveoli with the shortest time constants without improving gas exchange. Recruitment of alveoli with longer time constants may be achieved by adding an end-inspiratory pause or by prolonging the inspiratory time.

## Tracheostomy and endotracheal tube ventilation

### Composition of tubes

Rubber tubes were used for many years but they tend to perish and are irritant, probably because of the sulphides they contain. As a result most modern tubes are made of silver or synthetic materials. Silver tubes are light and inert and their thinness increases the ratio of internal to external diameter. They also have efficient low-resistance speaking valves. They are expensive but durable. Most modern endotracheal and tracheostomy tubes are synthetic, usually plastic, acrylic, silicone or PVC. They are virtually non-antigenic and most are thermoplastic so that they adapt to the shape of the patient's airway once they are in place. This pliability reduces the risk of tracheal injury. Polyurethane armoured tubes contain a coiled steel spring that prevents them kinking at sites of pressure such as close to the teeth.

### Length and diameter of tubes

An endotracheal or tracheostomy tube should be no longer than anatomically required so that its dead space is reduced to a minimum. A tube that is too long may enter one or other main bronchus, usually the right, so that only this lung is inflated and the other collapses. Conversely, if

the tube is too short the cuff may damage the vocal cords and the tube may become displaced. Translaryngeal and tracheostomy tubes have a significant resistance which, if airflow is laminar, increases in inverse proportion to the fourth power of the radius. A slightly narrower tube therefore has a disproportionately large effect on airflow resistance. With narrow tubes it may be difficult to obtain an adequate seal with the tracheal wall when the cuff is inflated. However, larger tubes are more likely to traumatize the trachea and larynx and make it more difficult to speak. In general, the diameter of an endotracheal or tracheostomy tube should not exceed two-thirds the diameter of the trachea.

### Special tube features

Some tracheostomy tubes have a fenestration or hole in the outer tube that is designed to lie in the tracheal lumen to assist expiration of air through the vocal cords and upper airway during speech and weaning (Fig. 58.4).

Inner tubes are not a feature of translaryngeal tubes but are useful for tracheostomy tubes when these are likely to be required for prolonged periods. The inner tube is slightly longer than the outer tube and as a result secretions accumulate on it rather than on the outer tube. The inner tube can be removed and cleaned, usually twice daily, so that the outer tubing needs to be changed less frequently than would otherwise be the case. The inner tube occludes any fenestration and attaches to the ventilator connections and speaking valves.

### Cuffed and uncuffed tubes

Cuffless tubes were used almost exclusively before the

**Fig. 58.4** Synthetic tracheostomy tubes. Clockwise from bottom left: uncuffed fenestrated, non-fenestrated, cuffed fenestrated, non-fenestrated.

Copenhagen poliomyelitis epidemic of 1952 [9], but since that time they have been largely superseded by cuffed tubes. Nevertheless, cuffless tubes have the advantages that pressure necrosis of the tracheal wall due to the cuff does not occur. It is easier to speak with a cuffless tube since it occupies less of the tracheal lumen than a cuffed tube.

Cuffless tubes are used in particular in neonates and young children, in whom tracheal damage can easily occur with a cuffed tube, and in adults when there is upper airway obstruction and no risk of aspiration. The most common situation is after laryngectomy, but they are also used during weaning from positive-pressure ventilation and in some patients for long-term tracheostomy ventilation when speech is required and aspiration is not a problem [10].

Cuffless tubes do not protect the airway and the leak of air during inspiration through the upper respiratory tract can be uncomfortable and poorly tolerated. For these reasons, cuffed tubes are more commonly used. The new low-pressure high-volume cuffs have superseded the older high-pressure low-volume cuffs and have greatly reduced the risk of tracheal damage. The pressure required within the cuff depends on the airway pressure during ventilation and on the pressure required to prevent aspiration of material into the tracheobronchial tree. This is determined by the relative diameters of the trachea and tube, the elastance of the cuff, and on the height of the column of secretions lying above the cuff and their density. The factor limiting cuff pressure is the circulation of blood through the tracheal capillaries, and therefore it should be kept below 25 cmH<sub>2</sub>O wherever possible. The pressure on the anterior wall of the trachea is usually greater than on the posterior wall because the latter is more distensible, and cuff damage is therefore usually greatest anteriorly.

### **Early complications** (see ref. 11)

#### *Pneumothorax, pneumomediastinum and mediastinal emphysema*

These complications occur in up to 5% tracheostomies.

#### *Incisional haemorrhage*

Troublesome postoperative bleeding occurs in about 5% of tracheostomies. The wound should be packed and if the bleeding persists surgical exploration may be required.

#### *Tube displacement*

This can be a serious complication if it occurs during the first 4–5 days postoperatively. It is usually the result of inadequate securing of the tube and may be precipitated

by a bout of coughing. A false channel anterior to the trachea can easily be created during attempts to reinsert the tube. This is best attempted using a fiberoptic laryngoscope or bronchoscope as a guide.

#### *Tube blockage*

This may be due to accumulation of mucus or blood within the tracheostomy tube and can usually be prevented by frequent suctioning.

#### *Tracheostome wound infection and tracheobronchial aspiration*

Aspiration is usually due to an inadequately inflated cuff.

### **Late complications**

#### *Tracheal stenosis and related complications*

These are most common in infants and elderly patients and if the cuff pressure is excessive, particularly if the tube is of wide diameter or moves excessively. Damage may occur at the site of the tracheostome itself, at the level of the cuff or at the tip of the tracheostomy tube, especially if the tube is too large or if it is positioned at an incorrect angle. The initial changes are loss of the ciliated epithelium and mucous glands and development of squamous metaplasia. Following this, the mucosa may ulcerate and the cartilage can be damaged. This leads to dilatation, the formation of a flaccid segment of trachea, or to fibrous stenosis. These complications may require resection of the affected segment, repeated dilatations or stenting.

#### *Tracheo-oesophageal fistula*

This occurs in less than 1% of tracheostomies and is due to necrosis of the posterior wall of the trachea. It is often associated with the presence of a nasogastric tube in the oesophagus. It should be suspected if food or other gastric contents can be aspirated from the trachea, if there is an air leak around the cuff associated with abdominal distension, or if an increasing amount of air is required to fill the cuff. Surgery is required to repair the defect.

#### *Tracheo-innominate artery fistula*

This is due to erosion through the tracheostomy anteriorly at the level of the clavicle. It may present with obvious pulsation of the tracheostomy tube or small (sentinel) haemoptyses. Repositioning of the tube or use of a tube of a different length may be required. Urgent surgical treatment is needed, although only about 25% of patients survive.

**Tube obstruction**

This is usually due to secretions and should be prevented by adequate humidification and frequent suctioning.

**Tracheobronchial aspiration**

This is usually due to use of an inadequate cuff pressure or inappropriate deflation of the cuff.

**Swallowing difficulty**

The presence of a tracheostomy tube may impair elevation of the larynx, which is required to open the cricopharyngeal sphincter and to enable swallowing to proceed normally [12].

**Tracheostome infection**

This is a common problem in intensive care units but is infrequent when long-term tracheostomies are cared for in the home.

**Mask and mouthpiece ventilation**

Nasal intermittent positive-pressure ventilation was introduced in the early 1980s and since then has become widely used [13]. The ventilators that are suitable are similar to those used with tracheostomies and endotracheal tubes, although humidification of the inspired air is usually not required since the air passes through the upper respiratory tract.

**Nasal and face masks**

Nasal ventilation is possible with cannulae that fit within the nose and which distend during inspiration to seal on to the mucosa. They may cause pressure areas and soreness and an alternative is a design that seals on to the external nares. However, this type of interface can become displaced and in general a mask is preferred [14]. The standard nasal masks are made of silicone and fit snugly around the nose (Fig. 58.5). It is important to select a mask of the correct width and length in order to minimize air leaks and the risk of pressure areas, particularly over the bridge of the nose. Some models have a foam nasal support that reduces the pressure in this area. The masks are secured by straps which are tightened gently. The tension should be equal all around the mask so that it fits closely. Some designs of headgear have soft cotton caps to increase the stability of the mask (Fig. 58.6).

Face masks surround the mouth as well as the nose, but otherwise they work on similar principles to nasal masks. However, the standard designs are less comfortable and less well fitting than the standard nasal masks. Face masks also have a greater dead space, with a risk of rebreathing, and tend to be more claustrophobic than nasal masks.

Individually made masks are an alternative to the standard models. They may be more comfortable and reduce the air leaks and the dead space. There are a variety of methods of constructing individually made masks, but most involve making a mould of the nose.

## Complications

### *Nasal ulcers*

Ulceration of the skin over the bridge of the nose is a common problem [15]. It is usually due to the mask being fitted too tightly or to prolonged initial use of mask ventilation before the skin has hardened (Fig. 58.7). The use of high airway pressures that require the mask to be tighter than usual in order to minimize air leaks may contribute to skin ulceration. Occasionally the ulcer becomes infected, usually with *Staphylococcus aureus*, and it may be difficult to continue with mask ventilation until the ulcer heals. It is important to try to prevent ulceration of the skin, although

once this is established it may be necessary to either protect the skin with Granuflex or change to an alternative method of ventilation such as nasal seals, at least temporarily.

### *Displacement of the mask*

This is usually the result of a poorly fitting or inadequately secured mask; some patients regularly remove the mask, particularly during sleep.

### *Air leaks around the mask*

These are usually due to poorly fitting or inadequately

**Fig. 58.7** Scar on bridge of nose and crusting inferiorly from use of two different nasal masks.

secured masks but may be difficult to avoid, especially with face masks. Air leaks may lead to conjunctivitis if they are directed into the eyes.

#### *Air leaks through the mouth*

These are a problem particularly if the pressure within the mouth is high or if the oral muscles are weak or inactivated, for instance during rapid eye movement (REM) sleep. A chin strap or collar may be required to help close the mouth, and attention to the head and neck position and ventilator settings is required. If these methods fail, a face mask rather than a nasal mask should be used.

#### *Upper airway and head symptoms*

These are related to the high flow or pressure of dry air entering the upper airway. A dry or blocked nose may develop but are less common than with CPAP. A dry mouth occurs particularly if there is a large mouth leak. Nasal symptoms often respond to a steroid inhaler and adjustment of the ventilator settings may be of help.

#### *Abdominal distension*

This is caused by air entering the oesophagus rather than the trachea. It is most common in patients with neuromuscular disorders in whom the pharyngeal pressure during inspiration exceeds that which the cricopharyngeal sphincter can withstand. The airway pressure is raised if the elastance or resistance of the lungs and chest wall is increased or if there is poor coordination between the patient and the ventilator. Frequent belching, nausea,

vomiting, abdominal distension and the passing of flatus may develop. Reduction of the peak airway pressure is usually indicated, although this may reduce the alveolar ventilation unless other adjustments are made to the ventilator settings. Better coordination between the patient and ventilator lowers the pharyngeal pressure and may relieve the patient's symptoms.

#### *Upper airway obstruction*

This may occur at any level in the upper airway between the base of the tongue and the larynx. The mechanisms are uncertain but probably include passive airway closure possibly related to the flow or pressure waveform in the upper airway and active contraction of the upper airway muscles [16]. It can be detected by ballooning of the cheeks or neck and by failure of the chest and abdomen to expand during the ventilator's inspiratory phase. It often causes an increased mouth leak and occasionally abdominal distension, particularly if the obstruction is at laryngeal level. Attention to the head and neck position, provision of a collar and improved coordination of the patient and ventilator's respiratory cycles may all be of help.

#### *Initiation of mask ventilation*

Patients who have never tried nasal or face mask ventilation often find it difficult to adjust to the mask and to the high flow of air required. After an initial explanation it is best to place the mask over the patient's nose or face in a comfortable position with a low inspiratory flow rate or pressure. The mask position is checked to make sure that there is little air leak around it. The tidal volume or pressure support level is gradually increased while the trigger

threshold is kept at a low level. Attention is paid to the patient's comfort and with reassurance the ventilator settings are adjusted in order to ensure adequate alveolar ventilation, that the patient feels enough air is being delivered and that the timing of inspiration and expiration is appropriate. The expiratory time is adjusted so that it is slightly longer than the patient's usual expiratory time in order to encourage triggering of the next inspiration. The headgear is then secured and further fine adjustments to the ventilator settings carried out, ideally in the light of continuous monitoring of oxygen saturation and transcutaneous  $P_{CO_2}$ .

### **Mouthpieces**

Positive-pressure ventilation through the mouth has never been widely used, possibly because of difficulties in developing a satisfactory mouthpiece [17]. The types of ventilator used are similar to those for nasal, face mask, tracheostomy and endotracheal tube ventilation. The inspired gas requires humidification since it bypasses the nose, which is the physiological air conditioner. The ventilator circuit usually needs careful mounting so that the mouthpiece is stable and does not become displaced.

A variety of mouthpieces have been developed but none are very satisfactory. Most include a flange that lies between the lips and the teeth. Plaster moulds of the upper and lower teeth can be taken so that mouthpieces can be fashioned to fit precisely, but in general those that contact the tongue or palate are poorly tolerated and lead to the production of excessive saliva. Mouthpieces are held in place by straps which operate on a similar principle to those of nasal and face masks; in some designs these form an external seal over the lips as well as stabilizing the mouthpiece.

### **Complications**

The main complications of mouth positive-pressure ventilation include the following.

#### ***Nasal leaks***

These are significant in around 50% of subjects but are determined by palatal function at least as much as by nasal patency. Leaks are also determined by mouth pressure, which varies with the elastance and airflow resistance of the lungs and chest wall. Nasal leaks can be reduced by nasal plugs or nasal clips.

#### ***Dental complications***

Mouthpieces may loosen teeth and change their position. This often results in an open bite or a gap where the

mouthpiece is positioned. This can be avoided by individually moulded dental acrylic bite plates, although a lip seal is needed with these as well to prevent any air leaks from the mouth. Dental development is particularly impaired in children below the age of 4 years.

#### ***Mouth leaks***

These are a problem particularly if there is weakness of the lips or cheek muscles, as in many neuromuscular disorders.

#### ***Abdominal distension***

The factors causing this are similar to those described for nasal and face mask ventilation.

### **Advantages and disadvantages of mask and mouthpiece ventilation**

A tracheostomy is indicated in order to bypass upper airway obstruction, to gain access to tracheobronchial secretions and, if the tube is cuffed, to attempt to reduce aspiration as well as to provide ventilatory support. The non-invasive techniques only achieve the latter but all have the advantage of not requiring an artificial airway, which impairs coughing, swallowing and speech, and they can be used intermittently. This makes them suitable for patients who are being weaned from ventilation or who require intermittent long-term use. However, they are unsuitable if the patient is unconscious, uncooperative or requires continuous ventilation for more than 2 or 3 days, or has a weak cough with profuse tracheobronchial secretions. Masks and mouthpieces do not protect the airway and a significant risk of aspiration is generally considered to be a contraindication to their use. Nasal ventilation is usually the method of choice, although a face mask may be required if air leaks through the mouth are a problem. Mouthpiece ventilation is an alternative and is also indicated for intermittent use during the day if the patient is almost completely dependent on the ventilator. The subject can take occasional ventilator breaths between spontaneous respirations. At night there is an increased risk of displacement of the mouthpiece relative to nasal and face masks unless the mouthpiece is carefully constructed.

### **Negative-pressure ventilation**

With all the negative-pressure techniques, the chest and abdomen are enclosed in an airtight rigid chamber; in most of the earlier designs the rest of the body up to the neck was also enclosed in the chamber [18]. The advantages of this are that chest wall expansion is not limited by contact with the sides of the negative-pressure device and

only one airtight seal around the neck is required. The first of these ventilators to be effective clinically was the 'iron lung' or tank ventilator developed by Drinker in 1928 [19]. This and subsequent modifications were widely used during poliomyelitis epidemics until the 1950s [9] but since then have been largely superseded by positive-pressure techniques. Negative-pressure systems comprise both the chamber, which interfaces with the patient, and a ventilator or pump that provides the source of energy to support respiration.

### Types of ventilator

Negative-pressure ventilators or pumps are pressure generators that work in the controlled mode. Most are servo-controlled and their speed of response determines how completely they adapt to changing air leaks. The extent to which the preset pressure is maintained in the presence of a constant leak also varies between ventilators [20]. The negative pressure required to ventilate each patient is determined by the elastance and resistance of the patient's respiratory system and the ventilator circuit. The peak negative pressure is in practice usually 30–40 cmH<sub>2</sub>O [21] but depends in part on the pressure waveform generated by the ventilator. The peak pressure required is least when a square pressure wave rather than a half sine wave is produced. Upper airway obstruction is a complication [22,23], probably related most closely to the peak negative pressure and therefore should be less of a problem with ventilators producing a square pressure wave. The frequency and I/E ratio should be adjusted to be comfortable for each patient and to facilitate coordination with the ventilator.

### Types of chamber

#### Tank ventilation

Most of the modern tank ventilators are constructed of aluminium although some are plastic. The patient's body rests on a mattress within the chamber and a headrest supports the head and neck and prevents kinking of the upper airway. In some tank ventilators the head or feet can be elevated and in others the whole tank can rotate 180° in order to facilitate postural drainage [24]. Some observation of the patient is possible through portholes, which also enable catheters and monitor leads to be passed and physiotherapy to be carried out (Fig. 58.8). This type of ventilator has the disadvantage that access to the patient is limited and it is large, heavy and expensive. There are few centres in the UK with experience in their use. An airtight, comfortable neck seal is difficult to achieve and patients often find it awkward to lie in one position for long periods.

#### Jacket ventilation

With jacket (wrap or poncho) ventilators the functions of rigidity and imperviousness to air are separated into two structures. An inner framework of metal or plastic provides the rigidity and this is covered by an airtight garment. This seals around the arms, neck and usually the waist. Some designs have a back plate and some include the legs as well as the trunk. The air within the jacket is intermittently evacuated by a pump similar to that used for tank and cuirass ventilation.

Jackets, like tank ventilators, do not restrain the

**Fig. 58.8** Tank ventilator: patient receiving physiotherapy while being treated.

expansion of the rib cage or the abdomen but can be awkward to put on and cold because of air leaks. They are slightly more efficient than cuirasses, although their greater size and cumbersome nature has restricted their use.

### Cuirass ventilation

The earlier cuirass models were often ineffective because they fitted poorly and were inadequately designed. Individually constructed cuirasses are much more comfortable and effective in reducing leaks and are less likely to cause pressure sores (Fig. 58.9). They should enclose the anterior abdominal wall, which is then able to expand during inspiration. Movement of the lateral aspect of the chest should also be unrestricted. Individually constructed cuirasses can be made to fit patients even if there is a severe thoracic deformity such as scoliosis [25] (Fig. 58.10), although the cuirass may need to be modified if the patient grows or changes in weight. They are light and durable and unlike nasal and face masks do not cause claustrophobia. They rarely cause abdominal distension via aerophagy but can induce upper airway obstruction,

particularly during REM sleep. This may be due to loss of tone of the upper airway dilator muscles or to loss of the normal sequence of activation of the upper airway muscles during inspiration. Obstruction can be minimized by lowering the peak airway pressure and by selecting a negative-pressure pump producing a square pressure wave.

## Acute respiratory failure

### Indications for ventilation

The most common indications for ventilatory support in acute respiratory failure are severe pneumonia, asthma, adult respiratory distress syndrome (ARDS) and acute infective exacerbations of chronic bronchitis and emphysema. There are no fixed criteria for initiating ventilatory support but in general this is required if the arterial blood gases are deteriorating, particularly if  $PCO_2$  is rising, and if the patient is becoming confused, distressed or hypotensive. In acute as opposed to acute-on-chronic respiratory failure, intubation is almost invariably required together with sedation with or without muscle paralysis.

**Fig. 58.9** Cuirass ventilator showing velcro attachment for back strap and connector for ventilator circuit.

Fig. 58.10 Cuirass in position on patient.

Patients with asthma have expiratory flow limitation that leads to an increase in the end-expiratory volume and pressure (auto-PEEP) unless the expiratory time is sufficiently prolonged for the tidal volume to be completely expired. In order to preserve an adequate expiratory time, the inspiratory time is shortened and the respiratory frequency reduced. A small tidal volume is required to minimize the risk of barotrauma, which correlates with the peak inspiratory pressure. PEEP may be required to overcome auto-PEEP.

Patients with pneumonia have an increased pulmonary elastance that may lead to high peak inspiratory pressures with a volume-preset ventilator unless this is pressure-limited. Pressure-controlled ventilation with a rapid respiratory rate may be preferable. Similar considerations apply to patients with ARDS, although if this is severe the

inspiratory time may need to be prolonged so that it is longer than the expiratory time (inverse ratio ventilation) in order to improve oxygenation and to recruit alveoli with long time constants. The disadvantage of this is that the mean intrathoracic pressure increases and this reduces cardiac output and may cause auto-PEEP to develop. At a low level this may be beneficial in holding open small airways but at higher levels can be associated with excessive hyperinflation.

The optimal management of acute infective exacerbations of chronic bronchitis and emphysema has not been established. In some studies approximately 25% of patients admitted to hospital required intubation and the survival to discharge from hospital was 60–75% [26,27]. Recently, non-invasive ventilation has been recommended as an alternative to intubation, but none

of the studies has shown any survival benefit [28–30]. However, non-invasive ventilation may allow intubation to be avoided in some patients, particularly those whose respiratory failure is not very severe and who do not have profuse secretions [28–30]. Ventilation with a face mask is usually preferably to a nasal mask because most of these patients have large air leaks through the mouth. It is important that the cause of the acute infective exacerbation is promptly and effectively treated while ventilation is being supported.

## Weaning

Weaning implies two separate but closely related processes: the termination of mechanical ventilation and the removal of any artificial airway. In general the indications for weaning are the opposite of those for initiation of mechanical ventilatory support, and the factors that prevent weaning are similar to those that cause respiratory failure and require ventilatory support. The most important of these factors are listed below.

**1 Respiratory drive.** This may be reduced if the level of consciousness is impaired by sedatives for instance, or if the patient is deprived of sleep. It is also reduced if there is a metabolic alkalosis or chronic hypercapnia.

**2 Respiratory pump.** Respiratory muscle function can be impaired by malnutrition, hypoxia, hypercapnia, acidosis, hypercalcaemia, hypophosphataemia and hypomagnesaemia.

**3 Airflow obstruction.** Hyperinflation increases lung elastance and places the inspiratory muscles at a mechanical disadvantage, as well as rendering them too short to generate their maximum force. Airflow obstruction also increases the resistive work of the respiratory pump.

**4 Alveolar disorders.** Pulmonary oedema, pneumonia and other alveolar disorders increase lung elastance and the work of breathing as well as impairing gas exchange.

**5 Metabolic demand.** This is increased if the patient is febrile or anxious.

**6 Cardiovascular effects.** Oxygen transport is reduced by factors such as anaemia, low cardiac output or hypoxia, which may lead to pulmonary vasoconstriction.

Most of these factors are amenable to treatment, which should be carried out before trying to wean the patient from the ventilator. In general, weaning should be attempted when the capacity of the respiratory pump exceeds the load on it. A variety of predictors of successful weaning have been suggested [31,32] but are of limited value; these include tidal volume greater than 5 mL/kg, forced expiratory volume in 1 s (FEV<sub>1</sub>) greater than 10 mL/kg, vital capacity greater than 10–15 mL/kg, maximum inspiratory pressure greater than 20–30 cmH<sub>2</sub>O, minute ventilation less than 10 L/min and maximum voluntary ventilation twice the resting minute ventilation. In practice an overall clinical assessment is

usually more accurate and it is particularly important to bear in mind the patient's level of consciousness and ability to cough and swallow before weaning is attempted.

Many patients can be weaned rapidly with a short trial of T-piece spontaneous breathing followed by extubation. This principle can be extended so that patients breathe spontaneously for gradually lengthening intervals over a period of days or sometimes weeks but receive ventilatory support in between. Alternatively, gradual weaning can be achieved not by intermittent spontaneous ventilation but by steadily reducing the degree of support that the ventilator supplies. Partial respiratory support techniques are suitable for this method of weaning [33,34]. With assist control, for instance, the trigger threshold can be gradually increased and with IMV and SIMV the frequency of the machine breaths is reduced. With pressure support ventilation the pressure level is gradually lowered. In these ways the patient's work of breathing can be graduated and steadily increased. If weaning is delayed, non-invasive techniques, including nasal and face mask ventilation and tank ventilation, may be required, although in practice many patients undergo a tracheostomy before these techniques are used [35,36]. Non-invasive ventilation should not be used for weaning unless the patient's swallowing and coughing have been assessed or if there is upper airways obstruction.

## Long-term ventilatory support

### Indications

Long-term ventilatory support is usually indicated if respiratory failure causes troublesome symptoms, potentially serious complications such as polycythaemia or pulmonary hypertension or is likely to lead to these problems or to premature death. Symptoms may include frequent waking from sleep at night, feeling unrefreshed on waking in the morning, early morning headaches, daytime sleepiness and personality change, physical fatigue, breathlessness or ankle swelling. These symptoms can be effectively relieved by both positive-pressure and negative-pressure ventilation [37]. Long-term ventilation has also been attempted prophylactically in patients with Duchenne's muscular dystrophy before ventilatory failure has developed but this has not proved to be of any benefit [38].

### Effects on prognosis

The effect of ventilation on prognosis has not been definitely established as there have been no long-term controlled studies. However, survival in neuromuscular and skeletal disorders with home ventilation is good, especially in scoliosis and non-progressive neuromuscular dis-

**Fig. 58.11** Actuarial survival during treatment with ventilatory assistance. (From Shneerson [49] with permission.)

orders [39–42] (Fig. 58.11). In rapidly deteriorating conditions the prognosis is determined not only by the ventilatory failure but also by other complications, such as bulbar dysfunction which may lead to aspiration pneumonia [43]. In chronic bronchitis, emphysema and bronchiectasis, the prognosis is worse than in neuromuscular and skeletal disorders [42,44–46]. The survival with tracheostomy or nasal mask ventilation is similar to that observed with long-term oxygen therapy using oxygen for 12 h or more daily [47,48]. However, comparisons between these studies are difficult, since it is uncertain whether patients started on oxygen and mechanical ventilation at similar stages in their natural history and none has controlled for smoking, which may have been more important than either of the treatments in influencing survival.

The prognosis for patients with the sequelae of tuberculosis, including those who underwent a thoracoplasty, lies between these two groups, presumably because these subjects have both a chest wall defect due to surgery and extensive lung disease as a result of the tuberculous infection [50]. Non-invasive ventilation has also been used successfully in selected patients with cystic fibrosis [51], particularly as a bridge to transplantation.

### Effects on quality of life

There are few studies of the effects of long-term ventilation on quality of life but the published reports suggest that this can be good [52–54], even in progressive neuromuscular disorders [55–57]. The quality of life is related less to the physical limitations than to the mental state of the patient. All the techniques for supporting ventilation do nevertheless interfere to some extent with the activities of normal life, and in some cases with the patient's self-esteem. Nocturnal support is less intru-

sive than continuous treatment and in general patients prefer non-invasive systems to tracheostomy ventilation [58].

### Physiological effects of treatment

The arterial blood gases can be improved both during the day and at night. This improvement is apparent within a few days, complete within around 1 month and, in the absence of progression of the underlying disorder, these values are usually maintained for several years [39,41,59,60]. The mechanisms by which the blood gases are improved are not clear, but the most important effects probably include the following.

#### Improvement of the respiratory drive

Ventilation can influence respiratory drive by lowering  $P_{aCO_2}$ , which reduces the cerebrospinal fluid bicarbonate level and thereby increases the response to hypercapnia. Hypoxic depression of the respiratory centres can also be reversed and restoration of a more normal sleep architecture relieves sleep deprivation and increases the respiratory drive through mechanisms that are largely unknown at present.

#### Relief of respiratory muscle fatigue

Muscle fatigue has been postulated as a cause of respiratory failure but it is more likely that the central respiratory control mechanisms adapt their output to prevent fatigue from developing. None the less, it is possible that ventilatory support provided in the long term, even if only at night, improves respiratory muscle strength, endurance or coordination so that spontaneous ventilation is more effective during the day.

### Other mechanisms

An improvement in chest wall compliance, caused by a reduction in the stiffness of the soft tissues of the chest wall (due to the restricted range of tidal movements) and also by a decrease in lung elastance via reopening of small airways, may contribute to the blood gas changes. Other effects of ventilation, such as improvement in ventilation-perfusion matching and relief of upper airway obstruction, are transient.

### Selection of method of ventilatory support

Patients with poor bulbar function impairing swallowing and coughing are at risk of aspiration and usually require a cuffed tracheostomy tube. A tracheostomy is also needed if there is upper airway obstruction that prevents the non-invasive techniques from being effective. However, these are preferable for patients without these complications and in whom support is required only intermittently. This is usually confined to the night-time but some subjects require some additional support during the day. If ventilation is required for more than about 16 h per day, tracheostomy ventilation may be more convenient than non-invasive techniques, particularly in young children. Patients who are totally dependent on the ventilator are usually best treated with tracheostomy ventilation.

The choice between a nasal or face mask positive-pressure system and negative-pressure ventilation can be difficult. Many patients with neuromuscular and skeletal disorders can be adequately ventilated by either method, and whichever is preferred by the patient should be provided. For patients with severe hypoxia and hypercapnia and with markedly abnormal respiratory mechanics, mask ventilation appears to be more effective than negative-pressure ventilation. If mask ventilation is selected, the question arises as to whether to choose a volume- or pressure-preset system. The former compensates better for abnormal respiratory mechanics since it delivers a fixed tidal volume but is less able to cope with leaks either around the mask or through the mouth. A pressure-preset ventilator should be preferred if leaks are a problem and usually if the patient has a strong respiratory drive or an erratic respiratory pattern. These instruments not only have better flow-triggering systems than volume-preset ventilators but also generate a higher tidal volume in response to continuing inspiratory effort during the machine's inspiratory cycle. However, pressure-preset ventilators are unreliable if the patient's respiratory mechanics change, for instance due to retained secretions, bronchoconstriction or changes in sleep stage or, in the longer term, with changes in weight or during infections. The addition of PEEP may be of use in patients with upper

airway obstruction causing sleep apnoeas in addition to ventilatory failure and if auto-PEEP is present and is significantly increasing the initial inspiratory work of breathing.

### Home or hospital care

Ventilatory support is almost invariably initiated in hospital, often in intensive care units, although long-term hospital care is rarely preferable once the medical condition is stable. Whether treatment in the home is successful depends on the ability of the patient, the family and other attendants or carers being physically able to manage the equipment and also on their understanding of how to use it and cope with any problems that may develop. It is important to assess the psychological state of the patient and the type and extent of support from his or her family before discharge.

Patients who require home ventilation often have other disabilities such as limb weakness that may prevent them from becoming independent in managing their equipment. The patient's previous ability to cope with stress and acceptance of the respiratory support equipment are two factors that predict whether the patient will be able to continue with ventilatory support. These issues are particularly important with the more invasive forms of treatment, especially those requiring a tracheostomy. It is important to try to motivate the patient and family by realizing not only what the outcome might be if treatment is discontinued but also the benefits likely to be obtained if treatment is successful.

Ventilatory support should be as safe in the home as in hospital if care is taken in stabilizing the patient's condition before discharge. Occasionally, deaths occur in the first few days after discharge but these are remarkably few in large centres [61].

An important aspect of home care is the degree of independence that it enables the patient to maintain. This should be encouraged while the patient is still in hospital by gradually transferring responsibility for the patient's care from the health professionals to the patient and family and other carers [62]. Before discharge it is important to assess all the practical aspects of care in the home and to make any necessary modifications and to anticipate any difficulties which might arise.

Care is usually cheaper if the patient is cared for in the home rather than in hospital. This is particularly so if non-invasive forms of ventilatory support are provided, but for patients with multiple disabilities, usually due to chronic neuromuscular disorders, home care can be more expensive [63]. The cost is mainly determined by the number and grade of carers required. There may be as many as 10 for a patient with a high cervical spinal cord lesion.

Once the patient has returned home, it is important that he or she knows how to cope with any problems that may arise. Ideally a hospital telephone helpline number should be available continuously. It is usually not necessary to monitor any physiological indices such as oxygen satura-

tion in the home, although regular clinical reassessment is essential since the patient's condition may alter and the ventilatory requirements change. All ventilators need regular servicing, and accessories such as nasal masks need replacing.

# LUNG TRANSPLANTATION

TIMOTHY W. HIGGENBOTTAM

Clinical lung transplantation, which developed during the 1980s [1], has awakened interest in many hitherto neglected chronic lung diseases. Its emergence not as an experimental but as a clinical treatment has not only spurred our understanding of the new diseases associated with the transplant lung, but has also seen the introduction of new alternative medical and surgical treatments of chronic lung disease.

## Philosophy of lung transplantation and its consequent limitations

The replacement of diseased organs with healthy engrafted ones offers a number of therapeutic opportunities for the patient with chronic lung disease.

1 It enables replacement with lungs able to provide adequate ventilation and gas exchange in patients with respiratory failure [2].

2 Where there is advanced pulmonary hypertension, a normal pulmonary vascular resistance can be restored [3].

3 Extensive lung sepsis, as in cystic fibrosis, can be treated by removal and replacement with relatively clean and uninfected bilateral lung grafts [4].

It is important to understand that a transplant patient has traded the old diseased lungs for engrafted organs that to varying degrees are involved in an alternative chronic disease, namely lung rejection. Depending on the adequacy of control of rejection with immunosuppressive treatment, the normal function of the graft will decline over time and most transplant patients are ultimately likely to die of a transplant-related disease [5].

Donation of organs, except in the case of living related donors (see below), requires that a person has to die. An obligation of the transplant doctor is to make the most effective use of this precious gift. Presently, the need in lung disease is to extend the life of a fatally ill patient. Selection of patients involves the most careful assessment of their untreated chances of survival, and this is then compared with the chances of survival after the lung

transplant. Study of the natural history of many chronic lung diseases has been stimulated by this need [6].

Human donation of organs for transplantation can clearly never offer sufficient transplants to treat a significant number of patients with chronic lung disease, and thus only a selected few can benefit. This realization has spurred the quest for xenograft or animal organ transplantation and, more recently, has encouraged thought of cloning organs from single stem cells.

## History

Few of the early lung transplant recipients treated during the 1960s survived more than a few days. Technical problems with the surgery, acute lung injury of the engrafted lung and poorly effective immunosuppressive treatments all contributed to these failures [7].

In 1979 the first reports appeared of the use of cyclosporin as an immunosuppressive drug in patients with liver and renal transplants. This fungal-derived antibiotic was significantly better than the earlier immunosuppressives, azathioprine and steroids. Cyclosporin was tried first in cardiac transplants and in 1981 its use was reported in lung transplantation [1].

The initial operation of choice was heart-lung transplantation, where the graft is made up of the heart and lungs harvested *en bloc* in a single exercise. This operation provides an immediately functioning heart even when the underlying disease is advanced. Pulmonary hypertension secondary to uncorrectable congenital heart disease is the main indication for this form of surgery. Few centres worldwide are still using this method, as the alternative, double lung transplantation, allows the donor heart to be used separately in another cardiac recipient.

In the 1980s, Cooper developed the single lung transplant [8]. Initially used in patients with cryptogenic fibrosing alveolitis, this was soon extended for use in emphysema. *En bloc* double lung and, more recently, sequential bilateral lung transplantation are used in

patients with lung sepsis and in patients with primary pulmonary hypertension. The initial immunosuppressive treatment was with cyclosporin and steroids, azathioprine being added later. New therapies are coming into clinical practice each year offering fewer side-effects and better immunosuppression. A major contribution to the advance of this form of surgery was the development of techniques in medical management that allowed early diagnosis of complications, rejection and infection and simplified the patient's home care. These are described later.

## Indications

All forms of life-threatening chronic lung disease can be treated with this form of treatment.

### Emphysema and chronic obstructive lung diseases

These cause respiratory failure, and patients often die of intercurrent pneumonia or hypercapnic respiratory failure. Over the last decade there have been several studies of the natural history of these diseases. An adult with a forced expiratory volume in 1 s (FEV<sub>1</sub>) of less than 1 L or under 25% of the predicted value has only a 30% chance of surviving untreated for 3 years. However, medical treatments, specifically long-term oxygen therapy, can double the survival chance in those patients with an FEV<sub>1</sub> of less than 1.5 L, Pao<sub>2</sub> less than 6.5 kPa (50 mmHg) and Paco<sub>2</sub> greater than 6.5 kPa (50 mmHg).

Patients are now selected according to their FEV<sub>1</sub> values and when long-term oxygen therapy is no longer effective or cannot be considered because of the risk of hypoventilation causing significant hypercapnia. An alternative surgical treatment that should now be considered is lung volume reduction surgery for patients without respiratory failure where diffuse disease is observed on high-resolution CT (HRCT) [9] (see Chapter 23). HRCT is used prior to consideration of lung transplantation, not only to confirm the diagnosis of emphysema but also to detect evidence of bronchiectasis. This renders single lung transplantation unsatisfactory, as infection can spread from the native to the engrafted lung. Therefore the finding of bronchiectasis requires bilateral lung transplantation.

### Pulmonary fibroses

To the specific condition of cryptogenic fibrosing alveolitis one can add other forms of diffuse lung fibrosis, including sarcoidosis and diffuse fibrosis associated with the connective tissue diseases including scleroderma, as suitable for consideration for transplant surgery.

The characteristic feature of advanced lung fibrosis found in these conditions is the poor prognosis. In cryptogenic fibrosing alveolitis only a few patients make any sig-

nificant response to medical treatment. When decline in lung volumes or diffusing capacity for carbon monoxide (DLCO) occurs in an otherwise suitable patient despite appropriate corticosteroid and immunosuppressive therapy, it is wise to refer early in the progression of disease for consideration for surgery [10]. As noted in Chapter 31, a number of patients with cryptogenic fibrosing alveolitis show rapid progression and if such patients are not controlled with limited doses of corticosteroids they also should be referred early for consideration for transplantation.

Ideally there should be histological proof of diagnosis in patients with diffuse lung fibrosis, as a number of diseases can be difficult to differentiate from cryptogenic fibrosing alveolitis (see Chapter 31). In explant lungs the author has observed *Mycobacterium tuberculosis*, plexogenic pulmonary hypertension and carcinoma in clinically diagnosed patients.

### Primary pulmonary hypertension

The natural history of this disease is now well described and the effectiveness of medical treatments known (see Chapter 26). This has allowed a straightforward approach to selection of patients for surgery [10]. The prognosis can be determined by the haemodynamic measurements obtained at a diagnostic right heart catheter study and from this analysis treatment can be determined [11].

1 Medical treatment in the form of anticoagulation is offered to all patients. This improves survival, presumably by reducing intravascular pulmonary thrombosis.

2 In those patients with a right atrial pressure below 2 kPa (15 mmHg), a cardiac index above 2.1 L/min/m<sup>2</sup> and an S $\bar{v}$ O<sub>2</sub> of more than 63% and in whom there is a capacity to vasodilate when given prostacyclin, a potential treatment is an oral calcium channel blocker such as diltiazem. Given in a dose to maintain a systemic arterial pressure of 100/70 mmHg, this often improves symptoms and survival.

3 When the patient has developed right heart failure, i.e. right atrial pressure greater than 2 kPa (15 mmHg), cardiac index less than 2.1 L/min/m<sup>2</sup> and S $\bar{v}$ O<sub>2</sub> less than 63%, a continuous intravenous infusion of either prostacyclin or iloprost (a stable analogue) improves survival and quality of life.

Lung transplantation is considered when this sequence of medical treatment fails to control symptoms and where there is evidence that the disease is progressing. It has been suggested that prostacyclin and iloprost can achieve 5-year survival rates of 80%, which exceed the rates seen with transplantation [11,12].

### Cystic fibrosis

Lung transplantation has contributed to the unravelling of

the genetics of this common inherited disease (see Chapter 30). It was demonstrated early in the 1980s that when patients with cystic fibrosis underwent heart–lung transplantation the typical mucosal abnormality of ion transport did not recur in the engrafted lung [13]. This excluded notions of a contributing humoral factor and placed the pathogenic emphasis on the mucosa.

The main prognostic measures in advanced cystic fibrosis are FEV<sub>1</sub> values below 25% of those predicted, arterial hypoxia with  $P_{aO_2}$  values below 6.5 kPa (50 mmHg) and, most importantly, an elevated  $P_{aCO_2}$ , which provides evidence of hypoventilation. Hypoventilation carries a poor prognosis [14].

Patients can be considered for transplantation before the development of respiratory failure when there is a history of life-threatening haemoptysis or uncontrolled pulmonary sepsis. In these circumstances a careful appraisal of the patient is required, weighing up the relative risks of the underlying pulmonary problem and the risks from lung transplantation.

### Tumours

There is only limited information on the outcome of lung transplantation on patients with cancers. However in other forms of solid organ transplantation it is recommended that 5 years' freedom from the original cancer should elapse before transplant surgery is considered [10]. This advice precludes the use of lung transplantation as a treatment for all forms of lung cancer. Certainly case reports indicate a high recurrence rate for even tumours of low malignancy such as alveolar cell carcinoma [10].

One special indication for lung transplantation is the development of diffuse lung fibrosis as a result of chemotherapy for lymphomas. Again the empirical advice is to wait for a 5-year period of freedom from relapse before surgery is considered.

### Lung transplantation in children

The results of lung transplantation have been poorer in children, considered as a group, than in adults. This has been the result of higher incidence rates of pulmonary infections and greater difficulty in the diagnosis and treatment of acute lung rejection [15]. However, in the child with advanced lung disease transplantation offers an effective treatment. The main indication is pulmonary hypertension, either primary or secondary to congenital heart disease or pulmonary dysplasia. A number of children with cystic fibrosis require transplant surgery, although the usual age range for transplantation in this condition is 18–25 years.

Assessment of the patient's untreated survival chances is undertaken in the same way as in the adult. The recom-

mendation is that this is performed in a unit specializing in childhood lung transplantation.

## Surgical techniques

### Heart–lung transplantation

The era of lung transplantation began in 1981 with the successful use of heart–lung transplantation (HLT) for pulmonary hypertension [1]. After excision of the heart and lungs of the donor *en bloc*, the trachea is anastomosed in the recipient just above the carina. The integrity of the anastomosis is maintained as a result of extensive collateral arterial blood supply to the lower trachea from the coronary arteries. Airway complications had been a major limiting factor in earlier attempts at lung transplantation. The advantages of HLT include the benefits from simultaneous engraftment of the heart, allowing immediate restoration of normal cardiac output, an important factor in patients with severe pulmonary hypertension.

The operation requires cardiopulmonary bypass. As a result, there is an age limit for patients of 55 years. There is also a significantly higher risk of perioperative bleeding despite the introduction of aprotinin to limit this complication. Further disadvantages are that the heart can also be involved in chronic rejection, although this is not isolated from the same process in the lungs. The use of both lungs and heart limits the number of potential recipients who can benefit from the donation. The 'domino' operation, where the recipient's heart is used and donated to a second recipient, is one way of maximizing effective use of the organs [16].

As a result of the limited number of donors, most centres have confined HLT to the treatment of pulmonary hypertension secondary to uncorrectable congenital heart disease. However, certain centres have retained HLT for cystic fibrosis and primary pulmonary hypertension. Internationally the results are poorer from HLT than from other forms of lung transplantation [15].

### Single lung transplantation

Single lung transplantation was first used to treat cryptogenic fibrosing alveolitis but quickly gained a place also for emphysema [9]. Its advantages are that potentially two lung recipients and one cardiac recipient can be treated with organs from one donor. No cardiopulmonary bypass is needed and so patients up to the age of 65 years are being considered for this form of transplantation. Perioperative bleeding is limited.

A number of technical innovations to achieve good healing of the bronchial anastomosis have been tried. These include wrapping the omentum around the suture line or telescoping the donor bronchus into that of the recipient. Each approach has its advocates but careful har-

vesting of the graft appears equally important in determining successful outcome. It is essential to exclude bronchiectasis in patients with either cryptogenic fibrosing alveolitis or emphysema, as the remaining native lung infects the transplant and compromises the chances of success. HRCT is the test of choice.

Operations for single lung transplantation in patients with emphysema involve selection of donor lungs that have a total lung capacity (TLC) to match that predicted by the height and age of the recipient. After surgery the lungs adopt the size determined by the thoracic vertebral height; as a result a patient with emphysema has a reduction in TLC, while in cryptogenic fibrosing alveolitis the TLC increases [17]. This nicely demonstrates an important physiological point, namely that the volume of the lung is determined by the size of the thoracic cavity.

### Double lung transplantation

This operation is now performed as two sequential lung transplants, one side followed by the other. There usually is no need for cardiopulmonary bypass. Again the risk of bleeding is less than in HLT. This is the operation of choice for cystic fibrosis and bronchiectasis, and is also now advocated for patients with primary pulmonary hypertension [18]. Single lung transplants are used in some centres for this disease, although acute pulmonary oedema in the postoperative period and disabling breathlessness if obliterative bronchiolitis develops in the graft limit the efficacy of this operation. Again the opportunity to use the donor heart for another cardiac recipient is retained.

### Living-related donation of lungs

The delays in obtaining donor organs and the rapid decline in the clinical state of children with cystic fibrosis awaiting a lung transplant led to the development in California of the procedure of living-related donation [19]. Both parents of a cystic fibrosis child donate a lobe of lung, which are then tailored to fit into the thorax on each side. The risks to the donor have been determined to be small and the engraftment is no worse than with cadaveric transplant. The need for close matching between the donor and recipient is not necessarily a limiting factor, as more distant relatives than parents have been used as donors. This procedure has been mainly restricted to children with cystic fibrosis.

### Selection criteria

Patients evaluated for lung transplantation should have received maximal or optimal medical treatment for the disease but nevertheless have declining lung function. Lung transplantation is rarely an option for the acutely ill

patient requiring intensive care. Concurrent illness should be adequately treated and preventative care instituted for common illnesses [10].

Older patients survive less well than the younger transplant patient. Currently the maximum ages advised for surgery on the basis of survival chances are 55 years for HLT, 65 years for single lung transplantation and 60 years for double lung transplantation. Certain medical conditions that affect the results of lung transplantation can be considered to be contraindications if untreated, and some of these remain absolute contraindications. Current corticosteroid therapy is not a contraindication, but the dose should be reduced to 20 mg or less per day.

For every patient an individual assessment is needed and careful counselling is required. Most centres admit the potential recipient for a period of time to engage all the specialists involved and to undertake appropriate tests.

### Relative contraindications

- 1 Symptomatic and asymptomatic osteoporosis require treatment before transplantation of the lungs. This requires full investigation and appropriate objective measurements of improvement by bone densitometry.
- 2 Severe musculoskeletal disease of the thorax.
- 3 Obesity or cachexia; weight needs to be between 70 and 130% of the ideal.
- 4 Substance abuse, including nicotine, alcohol and narcotics. Freedom from abuse for 6 months is needed.
- 5 Psychosocial problems must be resolved before surgery.
- 6 Requirement for invasive ventilation is a relative contraindication but this is not applied to patients on non-invasive ventilatory support.
- 7 Colonization with fungi and mycobacteria are not absolute contraindications but special care needs to be observed where single lung transplantation is considered.

### Absolute contraindications

- 1 Major dysfunction of another organ, such as liver or kidneys, precludes lung transplantation, unless combined multiorgan transplantation is considered.
- 2 Progressive neuromuscular disease.
- 3 Infection with human immunodeficiency virus (HIV).
- 4 Infection with hepatitis B (antigen positivity) and hepatitis C with liver disease.

### Donor selection and lung preservation

Selection of donors has become a critical part of the lung transplant programme. Less than 30% of potential donors can contribute lungs, a situation quite unlike that with other solid organ transplants. This reflects the frequency with which the lungs are infected or oedematous in

patients who have died from brain injury or stroke. Patients cannot become donors if positive for HIV or hepatitis B or C nor if they have evidence of malignant disease.

Lung donors are confined to people who have been non-smokers under the age of 45 years. The ideal lung donor should have a clear chest radiograph, normal gas exchange and no evidence of pneumonia. Most centres send out teams to manage potential donors in order to reduce the risks of fluid overload and to check for pneumonia prior to death. Assisted ventilation is optimized before the harvesting operation.

The donor operation involves cannulation of the pulmonary artery and infusion of either prostacyclin or prostaglandin E<sub>2</sub> [20]. This causes vasodilatation of the pulmonary circulation in order to allow the cold preservation fluid to be subsequently distributed through the lungs. It may also have some cytoprotective effects. The lungs and heart or heart–lung block are preserved inflated at 4°C. A number of different types of preservation fluid are used but all are limited to total ischaemic times below 4 h. If this time is exceeded, the engrafted lungs develop significant reperfusion injury.

Donors and recipient are matched according to ABO blood group. Usually cytomegalovirus-positive donors are matched with positive recipients.

## Perioperative care

Intravenous immunosuppressive treatment is given before surgery in the form of cyclosporin, azathioprine and steroids, which are continued postoperatively until food is taken by the patient. Early extubation, allowing the patient to breathe spontaneously soon after surgery, is the ideal. Mobilization and oral feeds are started as soon as possible. The main limitation to this is acute lung injury after surgery and this usually occurs as a result of surgical complications. Patients are given broad-spectrum antibiotics and fluid is restricted to avoid pulmonary oedema. Nursing takes place in a separate intensive care area, although isolation is no longer practised. Once mobilized, the patients can return to general wards.

## Management of complications

There are two main acute complications: infection and rejection of the lung. These occur most frequently in the first postoperative months but can occur at any stage of the transplant. Many of the early developments in lung transplantation focused on the diagnostic techniques and methods of monitoring graft function.

### Daily spirometry

For adults, both acute rejection and infection of the trans-

planted lungs cause a fall in FEV<sub>1</sub>. Using daily measurement with a pocket spirometer it is possible to detect the complication before chest radiographic abnormalities develop [21]. The fall in FEV<sub>1</sub> is an indication, along with the respiratory symptoms of breathlessness and cough, for undertaking a transbronchial lung biopsy and bronchial lavage.

### Transbronchial lung biopsy

It was early realized that histology of small lung biopsies of the lung transplant is able to differentiate lung infections from acute lung rejection [22]. Characteristically the histology in rejection shows a perivascular infiltrate of activated lymphocytes. Occasionally the bronchioles are also involved in a similar infiltration. Treatment is with daily intravenous methylprednisolone (0.5–1 g) for 3 days followed by oral prednisolone in reducing dosage over 3 weeks. The lymphocytic infiltration clears with this treatment.

Common opportunistic infections can also be recognized from the histology of the biopsies. In cytomegalovirus pneumonia there are characteristic inclusion bodies in the epithelial cells. A foamy intra-alveolar exudate is seen in *Pneumocystis carinii* pneumonia. Herpes simplex infections also have characteristic inclusions. Bronchial lavage allows further cytological examination and culture for bacterial infections.

### Immunosuppressive treatment

The principal immunosuppressive treatments are cyclosporin [8] (or the equivalent tacrolimus [23]), azathioprine (or mycophenolate [24]) and oral prednisolone. The doses of cyclosporin or tacrolimus are monitored by means of blood levels of the drug. Renal function is carefully monitored as both cyclosporin and tacrolimus injure the kidneys. The white cell count is maintained at  $6 \times 10^9/L$  if azathioprine is used. There are a large number of new immunosuppressive treatment regimens under investigation [25] and the pattern of treatment will certainly change over the next few years.

### Prophylactic antibiotic and antiviral treatment

All patients receive immediate prophylactic postoperative antibiotics. After 2 days, guided by the cultures of the bronchial aspirate from the donor lungs, further antibiotics are given. Patients receiving organs from a donor with positive serology to *Toxocara* spp. receive pyrimethamine postoperatively [1].

During periods when augmented immunosuppression is used to treat acute rejection, it is useful to cover patients who received organs from a cytomegalovirus-positive donor with intravenous ganciclovir. Oral co-trimoxazole

is used in the same way to avoid *P. carinii* pneumonia during augmentation of immunosuppression.

## Results

### Heart–lung transplantation

The outcome of HLT is that most patients attain their predicted normal values for FEV<sub>1</sub>, vital capacity and TLC within 3 months of the surgery [26]. Their exercise tolerance is not as good as predicted for their height and age, probably as a result of the denervated heart being unable to increase cardiac output equivalently to normal [27]. In contrast, denervation of the lung affects neither control of breathing nor the perception of breathlessness. Indeed bronchoconstriction can be demonstrated in the transplanted lung, particularly at times of acute rejection when bronchial hyperresponsiveness as seen in asthma is well described. In all these functions, vagal innervation of the lungs appears unimportant [28].

### Single lung transplantation

As one native lung remains, the improvement in lung function is less impressive than with double transplantation or HLT. However the FEV<sub>1</sub> and TLC return towards normal and the exercise tolerance often exceeds that seen after HLT [9].

### Double lung transplantation

These patients benefit from two lungs and retain a normally innervated heart. Lung function is normal and exercise capacity exceeds that seen after HLT.

## Later complications

A number of chronic complications limit the success of lung transplantation and contribute to early deaths.

### Airway anastomosis

Tracheal and bronchial dehiscence are recognized complications of poor vascularization of the anastomoses. While uncommon in HLT, errors in surgical technique in single and bilateral lung transplantation are punished by this problem. Diagnosis is by a combination of bronchoscopy and HRCT. Conservative management is the only successful approach, but fatalities are common.

More common in single and bilateral lung transplantation are the complications of either bronchial stenosis or bronchomalacia. The diagnosis is made by bronchoscopy and treatment is with expandable Gianturco stents. These complications are both the result of ischaemia of the anastomosis.

## Obliterative bronchiolitis

This is the most common cause of late death from lung transplantation and contributes significantly to morbidity after surgery. It is estimated that in 5 years one-third of patients die from this complication, one-third are disabled by it, while the remainder remain free of the problem [5]. The principal risk factor appears to be the frequency of acute rejection in the first 3 months after surgery [29]. Some have also implicated infection, as with cytomegalovirus. The abnormality is a proliferative obliteration of the bronchioles by a fibromuscular process [30]. It is often associated with bronchiectasis and suppurative airway disease [31].

The functional consequence of obliterative bronchiolitis is irreversible airways obstruction, characterized by a progressive fall in FEV<sub>1</sub>. Augmentation of immunosuppression can limit the rate of loss of function but seldom restores lost FEV<sub>1</sub>. A simple descriptive scheme of the disorder depends on the degree of fall in FEV<sub>1</sub> and is called the bronchiolitis obliterans syndrome grading [26]. It has predictive value for survival. Presently the only preventive treatment that has been shown to work is the use of nebulized budesonide, an inhaled corticosteroid, usually effective in asthma. When this is given for a year in daily doses of 500 µg to patients experiencing more than three rejection episodes in the first 3 months, it not only prevents obliterative bronchiolitis but also reduces the patient's requirements for oral prednisolone [32].

## Effectiveness and costs

There has been sufficient time to observe the long-term effectiveness of lung transplantation in extending life and improving the quality of life. However there have been no randomized controlled trials of transplantation nor any direct comparisons with medical treatments. The few studies of the quality of life after transplantation have in the main been descriptive rather than analytic. Studies of cost are now being undertaken and some preliminary work has been reported.

## Survival

There are differences in the ability of HLT and single and bilateral lung transplantation to extend life. These reflect frequency of use and the number of centres undertaking sufficient transplants to maintain skills. International registries report annually on outcome data [15]. There are ranges of values that should help the clinician decide on the merits of the operations.

- 1 HLT: 5-year actuarial survival 30–60%.
- 2 Single lung transplantation: 5-year survival 60–80%.
- 3 Bilateral lung transplantation: 5-year survival 50–70%.

The original disease also influences outcome. Emphysema provides the best survival figures for single lung transplantation. Primary pulmonary hypertension has the poorest survival figures from any type of lung transplant surgery in adults. Children also have poorer survival figures.

### Quality of life

Observational studies comparing patients before and after lung transplantation indicate substantial improvements for all three transplant operations [33]. Many of the measurements relate to activity and these correlate well with the enhanced exercise tolerance. Clearly all these studies focus on those patients who are well and do not systematically study those who have complications such as obliterative bronchiolitis.

### Costs

A few studies have addressed the costs of lung transplantation. Ramsey and colleagues [34] considered cost in relation to the improvement in quality of life. In particular, the cost per quality-adjusted life-year (QALY) was estimated. A figure for single lung transplantation in the USA was \$176 000 per QALY. Most of the costs concern the initial hospital costs, although a significant cost is incurred by complications such as bronchiolitis and infections. No such figure has been calculated in Europe. For comparison, in the UK the usual limit for cost-effectiveness of a new treatment is regarded as £25 000 per QALY [35].

One alternative approach to costs has been to consider the comparative costs of medical care, and this has been used to study cystic fibrosis [36]. Of interest, overall there was no cost reduction after lung transplantation surgery. Furthermore, there was no overall reduction in the number of admissions to hospital. These observations are of importance when a clinician advises the patient in making choices of types of care.

### The future

The prospects for lung transplantation are not limited by the costs but more by the availability of potential donors. It has been estimated that in the UK some 900 patients would benefit from lung transplantation each year. The total number of deaths from head injuries and strokes

where transplant organs could be donated is about 2000 per year [37]. Even with a perfect donation scheme there remains a large difference between the resource and the need. This has led to a number of strategies to increase the availability of transplantable organs.

### Xenograft transplants

The use of organs from another animal species has been prevented by an acute haemorrhagic injury, understanding of which has recently rapidly expanded [38]. It appears that there is an acute activation of complement, the process being facilitated by two receptors expressed on human endothelial cells, decay accelerating factor (DAF) and membrane cofactor protein (MCP). Research workers have overcome this by using transgenic animals, where the human receptors DAF and MCP are expressed on the endothelium of the pig [39]. Such animals can be used to donate hearts and kidneys, and it is possible that the lungs might also be used. Routine immunosuppressive therapy is still required to prevent the cellular and humoral rejection.

Sadly, however, this form of transplantation probably will not become a reality. There is evidence that the porcine genome contains retroviruses that are expressed in human cells when exposed to pig cells, and currently there is a moratorium on this form of transplant surgery.

### Cloning of organs

This has all the elements of science fiction. However the notion is that from a single cell it should be possible to develop a complete organ. Limited success has been reported experimentally with limbs and if achieved this would clearly offer the opportunity of using the patient's own tissue to develop a new organ such as a lung.

### Conclusion

We are entering the third decade of lung transplantation. New issues of cost and effectiveness need to be studied. Immunosuppressive therapies are improving, both in effectiveness and avoidance of toxic effects. Potentially new sources of organs may become available. After a prolonged stage of evaluation and experiment, lung transplantation is now established as an effective treatment for specific types of disease.

# TERMINAL CARE IN RESPIRATORY DISEASE

DOUGLAS SEATON

I have often thought upon death, and I find it the least of all evils.

*Francis Bacon (1561–1626)*

Death must be distinguished from dying, with which it is often confused.

*Sydney Smith (1771–1845)*

The inevitability of death, its unpredictability, the surprising perception that it can be regarded as a benign event and the important distinction between death itself and the process of dying are all germane to any consideration of medical care in its broadest sense; for no matter how hard we strive to educate ourselves about the prevention of disease and the provision of 'healthcare', all clinicians are, in the natural course of events, also responsible for the provision of 'dying care', and can do much good to patients and their relatives by a kindly and sensible approach to these matters. The opportunities for such care begin with the realization that the coming of death as a consequence of a firmly diagnosed disease is certain and not far removed in time and that increasing attention should be paid to the relief of suffering, both physical and psychological. It is at this point of realization that efforts may be turned away from the trials of investigative procedures or attempts at cure that rather than prolonging life may in reality be simply making the process of dying more protracted.

## Truthful explanation

The possession of the knowledge that a patient is dying gives the physician an opportunity to offer appropriate support to all concerned. Imparting this knowledge can be distressing for the patient and the family as well as the doctor, and how this is done is a delicate matter for which no simple formula exists. Events unfold according to circumstances so that sometimes the patient learns before close relatives, sometimes the reverse occurs and sometimes the truth is told to both together. It is common for the spouse or relatives to seek to protect the patient from the

knowledge that their disease is incurable and fatal. Such reactions are natural enough, particularly when voiced in response to the sudden realization of the true state of affairs. They may sometimes be right, at least for a time, but more often than not their judgement in this situation is inevitably clouded by emotion, for the deliberate concealment of the truth from the patient is an act of denial that increases the stresses between individual members of the family, the patient and the doctor, creating a world of make-believe in which interpersonal relationships become strained and in which suspicion, fear and mistrust are fostered. Family members who take this view may be reassured that in the doctor's experience patients who are denied the truth are likely to suffer more than those who have a greater awareness of their situation so that they can come to terms with it.

How patients are told that their illness is fatal is a matter of individual judgement. It is most difficult when the patient is outwardly in reasonable health, in which case the concept may be introduced gradually in terms of what can and cannot be done in the way of management. This often allows the patient to ask the relevant questions and to be supplied with answers that lead as far towards the truth as he or she wishes to go at that particular time. These disclosures should be made gently and by degree. A 'screening question' may be asked at the outset to try to establish the patient's perception of the position. The whole truth need not come out at first but a line of communication is set up so that the patient can establish trust in the doctor and in the authenticity of the information supplied, but can also be given time to adjust to the new situation that has arisen. This stepwise approach seems entirely reasonable and care should be taken not to 'assault the patient with truth' that he or she is not yet ready to handle [1]. Not infrequently the patient has realized the seriousness of the position and that recovery is not taking place. In this situation fairly frank explanations of the true state of affairs may bring a sense of relief, being received with openly expressed gratitude.

When the truth is told it should be accompanied by a

positive statement of the physician's intention to continue to offer supportive treatment and to deal with symptoms effectively whenever they should happen to arise. A failure to provide such assurances may produce a sense of abandonment and isolation stemming from the belief that 'nothing more can be done'. The provision of a firm statement of support may help to provide the patient with a much-needed sense of security and comfort despite the fact that life is drawing to its conclusion.

## Relief of symptoms

Although much can be done to relieve the physical and psychological symptoms of patients who are dying, there is evidence that our hospitals have fallen short of meeting basic needs [2,3]. The first step is to question the patient carefully about those symptoms that are most troubling. Where there is doubt in the presence of multiple symptoms, the principal symptom is usually easily sought out by asking the question: 'If there was one symptom that you could get rid of, which one would you choose first?' The answer frequently helps the physician to direct therapeutic efforts more usefully, while still taking account of secondary symptoms. A more formal symptomatic enquiry, system by system, may unearth other information of value in general management.

Whereas the event of death itself may be regarded as a merciful release, the process of dying can hardly be regarded as pleasurable, and the prospect of physical discomfort may produce a good deal of trepidation. Firm reassurance that uncomfortable symptoms will be effectively combatted may ease the mind of the worried patient. It is up to the individual physician to be sufficiently informed about the various therapeutic options available in order to fulfil such a promise. Clearly therapeutic intervention cannot abolish discomfort totally but it can nevertheless provide a considerable measure of relief.

## Pain

The perception of pain is entirely subjective and may well be influenced by mood, so that if individuals are depressed, anxious or lonely, painful sensations are likely to be more problematical than if their mood has been elevated by any of a number of circumstances, among which is included the provision of kind and courteous general care.

Having established that pain is present, some effort must be made to assess its significance. Patients may sometimes behave in a more reticent and stoical manner towards their medical practitioner than to other members of their family, and a clearer picture of the degree of incapacity caused by pain may be obtained from the spouse, partner or the nursing staff.

Once it has been established that pain is a problem, attention should be turned towards the likely cause. This can usually be inferred from the site and nature of the discomfort, which may be due to involvement of the chest wall, bones, nerves, nerve roots or brain. Patients with cancer more often than not have more than one pain and how far to investigate the source depends upon their general condition. In appropriate circumstances, plain radiographs, isotope bone scans or CT may be required. This is only the case if the result of the investigation is likely to influence management; for example, if it is suspected that there is localized involvement of bone or other structures that may respond to palliative radiotherapy. The instigation of adequate analgesia need not await the results of such tests. Patients are likely to benefit from a frank explanation of the cause of the pain, and if this is not forthcoming will only be worried all the more by doubt and uncertainty, whereas if they are clear about the mechanism then they will be better able to adjust and come to terms with it.

Although it is possible to grade pain according to a visual analogue scale and to record the degree of incapacity by devices such as the Karnovsky scale [4], from a practical standpoint, in patients with cancer, pain may be regarded as mild if it responds adequately to a simple non-narcotic analgesic such as paracetamol or aspirin, and moderate if it requires a weak narcotic analgesic such as codeine or dextropropoxyphene (commonly prescribed with paracetamol as co-proxamol). Any pain that is uncontrolled by the foregoing or is partly controlled but still significantly limits activity should be regarded as being severe and should be treated with a potent opioid (narcotic) analgesic such as morphine [5]. There is a plethora of analgesic preparations available and rather than wander randomly through a jungle of unfamiliar or less well-known preparations, it behoves the physician to develop a simple therapeutic 'three-rung ladder' (Table 60.1) and stick to it [6].

**Table 60.1** Vertical progression of oral analgesia in cancer-associated pain (see text).

	Same daily dose	Once or twice daily
Morphine sulphate (controlled-release preparations)		
Morphine sulphate (immediate-release preparations)	5–10 mg titrated upwards	Every 4 h
Co-codamol 30/500	Two tablets	Every 4–6 h
Codeine phosphate	30–60 mg	Every 4–6 h
Paracetamol	1 g	Every 4–6 h

### Lower rung

Paracetamol is a suitable lower-rung preparation often used for mild pain relief. Aspirin, which has both analgesic and anti-inflammatory properties, may be taken as an alternative at a dose of 600 mg every 4–6 h, although one of the many other non-steroidal anti-inflammatory drugs may be used instead. Aspirin intolerance may be reduced if it is taken after meals.

### Middle rung

Drugs belonging to the family of weak opioid analgesics, such as codeine or dextropropoxyphene, occupy the middle rung. Dihydrocodeine is a semisynthetic analogue that has no particular advantage over the standard weak opioid codeine. In the UK, dextropropoxyphene 32.5 mg is commonly prescribed in combined form with paracetamol 325 mg as co-proxamol. Combinations of codeine with paracetamol also exist and when these are used it makes sense to prescribe a formulation that contains a therapeutic 30-mg dose of codeine (co-codamol 30/500) rather than one of those containing only 8 mg (co-codamol 8/500), unless the patient is very elderly in which case increased sensitivity to codeine and other narcotics may occur. These middle-rung analgesics are likely to be more acceptable than morphine to patients earlier in their disease, and when taken in combined form with paracetamol are probably as effective as low-dose morphine.

### Upper rung

Strong opioid analgesics like morphine and diamorphine are on the upper rung of the analgesic ladder. Some physicians may feel a reluctance to prescribe regular opioids unless they regard the patient as 'terminal'. Any such fears are misplaced and morphine may be continued safely for many months if need be. Stepping sideways on a ladder has never been a very wise course of action and if a non-opioid or a weak opioid analgesic proves ineffective at standard dosage, there is no point in using another similar drug; one should rather go directly to a strong opioid such as morphine (referred to by Sir William Osler as GOM or 'God's own medicine').

The principles are that this drug is prescribed orally by preference, that it should be taken regularly to prevent pain from recurring, that the dose should be tailored upwards according to the patient's needs and that there is no upper dose limit; thus the patient's pain may require anything between 2.5 mg and 2500 mg every 4 h to control it, good control being commonly achieved with 250 mg daily or less.

Morphine may be dispensed as an oral solution (mor-

phine elixir), the prescription having to be written in full in order to comply with the law [7] and to avoid embarrassing delays and telephone calls from the outpatient pharmacist, for example 'morphine hydrochloride 5 mg, chloroform water to 5 mL'.

Alternatively there are now prepared proprietary formulations of morphine sulphate solution such as Oramorph oral solution in strengths of 10 mg per 5 mL and 100 mg per 5 mL. The amount to be dispensed must be written *in figures and words*, for example 'supply 200 mL (two hundred millilitres)', followed by the amount to be taken, for example '10 mL every 4 hours'.

The same applies to morphine sulphate 10 and 20 mg immediate-release tablets (Sevredol). There is no particular advantage in prescribing oral diamorphine rather than morphine itself, as the former is itself biotransformed to morphine and other metabolites. The advantages of parenteral diamorphine are outlined below.

Morphine 5 or 10 mg every 4 h is a reasonable starting dose for pain that is continuous, as is frequently the case with malignancy, although 2.5 mg may be preferred in an elderly or frail patient or one with renal insufficiency. This continuous type of pain should not be treated with as-required or prn prescriptions, unless these are used to augment a regular strong opioid analgesic should breakthrough pain occur between doses. Such top-up or rescue supplementation can be given as often as necessary (e.g. hourly) but is an indication that pain control is incomplete and that the regular 4-hourly doses need to be increased. Doses of morphine sulphate oral solution or tablets are therefore increased gradually according to response, the usual dose for control being 5–30 mg every 4 h, although as mentioned above sometimes very much larger amounts are required. A steady pharmacokinetic state is reached in about 24 h and the dose can therefore be adjusted daily. It is usual to increase the dose by 30–50% at each step and a double dose at bedtime helps to ensure sleep. An example of morphine dose titration is given in Table 60.2.

As frequent dosage can be tiresome for the patient and awkward for the ward, modified-release morphine sulphate tablets (5, 10, 15, 30, 60, 100 and 200 mg) provide a convenient alternative for maintenance treatment, once the patient's total daily dose requirements (including rescue doses for breakthrough pain) have been determined using the 4-hourly regimen, being prescribed *at the same total daily dose* but using a 12-hourly regimen (e.g. MST Continus) [9]. The top-up or rescue dose of immediate-release morphine should be one-third of the 12-hourly dose of MST Continus, this being equivalent to an extra 4-hourly dose (Table 60.2). Modified-release morphine sulphate capsules (30, 60, 90, 120, 150 and 200 mg) for once-daily dosing have become available more recently (MXL). The modified-release preparations tend to

**Table 60.2** Morphine dose titration: an example of initial treatment with a standard formulation leading to maintenance treatment with a twice-daily controlled-release formulation. (After O'Neill [8] with permission.)

Day	Doses given	Total on that day	Starting dose on next day
Day 1	10 mg 4-hourly, plus three 10-mg prn doses	90 mg	15 mg 4-hourly (90/6)
Day 2	15 mg 4-hourly, plus two 15-mg prn doses	120 mg	20 mg 4-hourly (120/6)
Day 3	20 mg 4-hourly <i>Pain is controlled, no breakthrough dosage required</i>	120 mg	
Day 4 and on	60 mg twice daily ( <i>controlled release</i> ) plus 20-mg prn doses (standard formulation) should breakthrough pain occur		

achieve an attenuated peak plasma level in about 2–4 h compared with about 1 h for the immediate-release preparations.

It is clear from the foregoing that 'normal' doses of narcotic analgesics, such as might be used for the short-term relief of postoperative pain, do not apply in the management of chronic pain associated with incurable cancer. Respiratory tolerance to these high doses develops [10].

#### Route of administration

When analgesics are required, the oral route should be used wherever possible as injections are inconvenient for patients and increase their sense of dependence on those who are taking care of them.

If the patient cannot swallow, then strong opioid analgesics should be given either as morphine suppositories (morphine sulphate or hydrochloride suppositories 10, 15, 20 or 30 mg) or by injection. In the lower dose range of morphine, buprenorphine 200–400 µg sublingually every 6–8 h is an alternative. Buprenorphine binds partially to opioid receptors and may block the access of full agonists, such as morphine, to the same receptors, thereby partially antagonizing its effect if taken concurrently. A transdermal formulation of the potent opioid analgesic fentanyl has been developed, being applied in the form of a cutaneous patch. These are changed every 72 h and are available in different strengths designed to deliver 25, 50, 75 and 100 µg of fentanyl per hour. The system appears to be effective but as with other controlled-release formulations, immediate-release preparations may still be required for breakthrough pain [11,12].

Diamorphine (heroin) tends to be preferred for injection in the UK as it is more soluble than morphine; 20 mL of water is required to dissolve 1 g of morphine, whereas

only 1.6 mL is needed to dissolve 1 g of diamorphine. It is an advantage to be able to give the same dose in a smaller volume in patients who need large doses of subcutaneous opioid [13]. There is no point in giving diamorphine orally as it is a prodrug of morphine. Diamorphine is only legally prescribable in the UK and Canada. Hydromorphone, which has now become available in the UK (so far only in oral form, 1 mg dose equivalent to 7.5 mg morphine), has similar properties and is used in place of diamorphine in the USA and elsewhere (where a parenteral form is available). When used subcutaneously, diamorphine should be given at one-third of the oral dose of morphine that had previously controlled pain satisfactorily, in order to achieve the same effect, whereas if subcutaneous morphine is used it should be given at half the oral dose. If intravenous morphine is used (e.g. in patients with peripheral venous shutdown or in those who already have intravenous access established for some other reason), the equivalent dose is one-third of that given orally [14]. It is not usual practice to give morphine intramuscularly in a palliative setting as subcutaneous injections are less painful. A fine 'butterfly' needle may be used for regular subcutaneous injections.

A syringe driver (such as a portable, pocket-sized Graseby type MS16A pump) is a very useful method for delivering diamorphine in the terminal phase when the patient is disinclined or unable to swallow, being less disturbing than repeated injections. It may also allay fears on the part of the relations that the last dose of a 4-hourly subcutaneous morphine regimen 'carried off' the patient should death happen to come shortly after such an injection. However, it is a mistake to use this form of treatment while the patient is still able to swallow comfortably. Diamorphine is available in 5, 10, 30, 100 and 500 mg ampoules. Water for injection rather than 0.9% saline should be used for strengths greater than 40 mg/mL in order to avoid precipitation. The pumps run at a preset rate measured in millimetres of syringe plunger movement per hour. Thus the diamorphine (and any other compatible medication that needs to be infused as well) may be made up with water or saline to 8.5 mL total volume, which when drawn up in a 10-mL disposable plastic syringe occupies 50 mm of barrel length. The driver can then be set to run at 2 mm/h, emptying its contents over 25 h. The syringe is connected to the patient by a disposable butterfly cannula with integral 60 or 100 cm tubing, the butterfly needle being bent to about 45° and secured on the upper arm, thigh, abdomen or chest with a light proprietary dressing such as OpSite or Tegaderm. The conversion from oral morphine to 24-h or, in this case, 25-h subcutaneous diamorphine is achieved by dividing the previous day's dose of oral morphine by three (Table 60.3). A list of drugs compatible with diamorphine is contained in the British National Formulary [14].

**Table 60.3** Approximate dose equivalence of some opioid analgesics to oral morphine.

	Ratio
Diamorphine orally	2:3
Diamorphine subcutaneous	1:3
Morphine intravenous	1:3
Morphine subcutaneous	1:2
Morphine per rectum	1:1
Hydromorphone orally	1:7.5

For the oral route morphine is preferable to diamorphine; for the parenteral routes diamorphine is preferable to morphine (see text).

### Bony pain and sequelae

Bone pain, like visceral and neuropathic pain, tends to be somewhat less responsive to narcotic analgesics. When pain is localized and caused by direct involvement of the chest wall by tumour or by bony metastases, palliative radiotherapy may be very helpful and can often be delivered as a single treatment to a painful area. Indometacin (indomethacin) or other non-steroidal anti-inflammatory drugs may be useful in controlling bony pain, presumably as a result of their inhibition of prostaglandins, which are released during osteolysis [15]. They may also be used to supplement a regular strong opioid in the same situation [16]. In the same manner these drugs are very effective in relieving the pain of hypertrophic pulmonary osteoarthropathy (see Chapter 41). Preliminary data exist to suggest that bisphosphonates, such as oral clodronate or parenteral pamidronate, might be helpful in reducing bone pain from metastatic disease [15,17].

Pathological fractures of long bones are fortunately an infrequent occurrence in lung cancer. When they do occur they are almost always situated in the femur or the humerus. An orthopaedic opinion should be sought unless the patient is very close to death, as otherwise internal fixation and postoperative radiotherapy need to be considered. Sometimes prophylactic internal fixation is carried out when a large lytic metastasis is found in a weight-bearing long bone, this again being followed by radiotherapy. Patients with spinal instability secondary to destructive metastatic bony involvement may require orthopaedic stabilization followed by radiotherapy.

Those with spinal cord compression may be treated by surgical decompression and stabilization or by radiotherapy or both. Surgery is more likely to be undertaken in those with paraplegia or urinary retention of less than 24 h duration, when the block on magnetic resonance imaging or CT involves less than three contiguous vertebral segments and when the patient's life expectancy is likely to be more than a few weeks [18].

### Intractable pain

Pain in lung cancer that persists despite treatment with large doses of narcotic analgesics is unusual, 80% of patients responding to the measures outlined above. Occasionally, pain is difficult to control and alternative methods may be required to achieve adequate relief. Morphine is usually effective in controlling 'tissue-damage' (or nociceptive) pain, in which the pain is produced by the stimulation of nerve endings in non-neural tissue, whereas it tends to be ineffective in neurogenic pain (e.g. trigeminal neuralgia, postherpetic neuralgia, thalamic pain and pain from brachial plexus involvement by tumour), in which impulses are produced as a result of neural dysfunction and do not follow classic pain pathways. The reasons for the occasional resistance of tissue-damage pain to the action of morphine may be related to the ratio of one of its opiate receptor-binding metabolites (morphine 3-glucuronide) to another (morphine 6-glucuronide) in different patients, the former tending to antagonize analgesic activity whereas the latter is itself a potent analgesic. Thus those with a high ratio of 3-glucuronide/6-glucuronide may be relatively resistant to the analgesic effect of morphine on nociceptive pain and may experience so-called paradoxical pain [19]. It has been suggested that these patients may be more responsive to methadone, which follows different metabolic pathways to morphine [20]. Patients with neurogenic pain may sometimes respond to a tricyclic antidepressant such as amitriptyline (for 'burning' discomfort) or to an anti-convulsant such as sodium valproate or carbamazepine (for 'shooting' pains). The analgesic effect of the tricyclic group appears to be unrelated to any antidepressant effect and these drugs (mixed reuptake inhibitors) seem to be more effective in this regard than the newer selective serotonin reuptake inhibitors such as paroxetine. The dose of amitriptyline should be started as low as 10 mg at night in order to improve patient acceptability, and should be titrated up at weekly intervals with proper explanation of its minor but tiresome adverse effects. Low doses in the range 25–75 mg nocte are usually settled for and an added benefit is a degree of nocturnal sedation. Failure of amitriptyline to control opioid-resistant neurogenic pain may then lead to the substitution of sodium valproate, titrating up from 200 mg twice daily to a maximum of 1600 mg daily or, alternatively, carbamazepine starting with 200 mg at night increasing to 400 mg twice daily according to tolerance and response [21]. Dexamethasone 8 mg daily may reduce oedema around tumours that are compressing nerves.

One non-invasive technique that can be beneficial in chest wall pain is transcutaneous electrical nerve stimulation (TENS), in which patients must be taught properly how to deliver an electrical stimulus from a small battery-operated device by cutaneous surface electrodes either to

the painful area itself or to the nerve roots subtending that area. The stimulus, which the patient must feel, is transmitted by myelinated fibres to the spinal cord, thereby blocking the transmission of pain signals according to the gate control theory of pain [22]. It is not easy to know which patients are likely to respond and any beneficial effect may gradually decline over some weeks.

Nerve blocks are a matter for the specialist in pain relief and are carried out in appropriate circumstances as a last resort; these procedures should be planned after due discussion with the patient and the close relatives. They involve the injection of a neurolytic substance such as phenol or alcohol into the immediate proximity of the appropriate nerve trunk or root, with permanent alteration of nerve function [23]. The likely effects, which may be motor as well as sensory, may be simulated if a local anaesthetic block is used first. Intractable thoracic pain may respond to paravertebral or intercostal nerve block. Another technique for nerve block involves the use of a cryotherapy probe. Clearly, the source of the pain needs to be accurately determined and the destruction of nervous tissue selective in order to relieve pain successfully and to avoid motor damage. Dorsal sensory nerve roots may be interrupted by radiofrequency thermocoagulation, a technique that can also be used to carry out a percutaneous spinothalamic tractotomy. The application of these specialized procedures depends upon local interest and expertise but are seldom required in the management of lung cancer.

### Side-effects of narcotic analgesics

Patients frequently react badly to the prospect of being prescribed strong opioid analgesics, fearing that such treatment will 'drug them up' and render them incapable of all normal activity. They can be reassured on this count but should be warned that they may feel some drowsiness for the first 3 days or so. Effects on cognition are minimal once patients have been established on a stable dose and such patients should be permitted to drive should they so wish [24]. However, they should not drive when morphine is being started or increased in response to worsening pain [25].

Nausea or vomiting should be anticipated and may occur at the onset of treatment in up to two-thirds of patients. This can be prevented by the use of cyclizine 50mg or metaclopramide 10mg, each taken three times a day before meals. Haloperidol 1.5mg at night or twice daily may also be effective. These symptoms often subside spontaneously so that it is possible to withdraw the antiemetic within a few days.

Constipation is an inevitable consequence and the main nuisance of opioid analgesics. It should always be anticipated, whenever these are used, by the use of regular laxatives and patients should be forewarned. This aspect of

management is important and is dealt with below in more detail.

### Cough

A cough causing distress in terminal lung disease requires symptomatic treatment and, in addition, an explanation of the cause of the cough, coupled with reassurance that it is not going to cause choking or suffocation; a description of how it can be dealt with does much to help the patient's flagging morale. Assuming that the patient is not already taking morphine, codeine linctus 30mg three or four times daily can be tried initially. Patients in whom this is ineffective may be started on morphine, which can be titrated against response in the manner described above for pain. Methadone may be effective for night-time cough as it has a relatively long half-life.

There are a number of other symptomatic remedies that may be tried for additional relief. These include inhalations of benzoin tincture, one teaspoonful of which is put in a pint of hot water and the vapour breathed in by the patient from a Nelson's inhaler. The sensation of warm moist aromatic air is comfortable and may assist difficult expectoration. Sometimes the patient may feel the presence of viscid sputum that has great trouble in breaking free and, if a moist inhalation is ineffective, carbocysteine or another mucolytic agent sometimes produces symptomatic relief, although the cost of such preparations may outweigh their benefit. Simple change of posture and physiotherapy may also help these patients, who may be advised to try lying with the affected lung uppermost in order to facilitate the drainage of obstinate bronchial secretions. Advanced bronchioloalveolar cell carcinoma may unusually produce extremely copious and salty-tasting sputum, the sheer volume of which provides the patient with an exhausting and unbearable problem that is best dealt with by regular and increasing doses of morphine.

Inhalations of nebulized solutions of local anaesthetic may prove effective in intractable cough where other measures have failed. They suffer from the disadvantage of anaesthetizing the mouth and pharynx so that fluids or food may be inadvertently aspirated if taken within 1 h of the dose. Lidocaine (lignocaine) up to 5mL of 2% solution every 6 h may be used; alternatively, bupivacaine 0.25% solution has been recommended at a dose of up to 5mL every 8 h [26,27].

### Dyspnoea and associated symptoms

As with other respiratory symptoms in the terminally ill, the advice that treatment for shortness of breath is available and effective and that support is at hand may provide reassuring comfort. Relaxation techniques and simple measures such as the provision of a fan may increase

comfort. Sometimes breathlessness in advanced malignancy may be treated by attention to the cause, such as those listed below.

1 Obstruction of a large central airway by tumour that may be responsive to radiotherapy, laser treatment or stenting (see Chapter 41). Stridor in this situation may also be temporarily relieved by breathing a commercially available mixture of helium and oxygen (4:1). Dexamethasone 16 mg daily may also help.

2 Restriction of the movement of the affected hemithorax by the presence of a pleural effusion, in which case relief may be obtained by thoracentesis (see Chapter 43). In both these cases the clinician has to make a judgement on whether active intervention will improve the patient's comfort. If the end is seemingly very close, then invasive measures are probably unwarranted. Sometimes surprisingly large effusions may occur in the absence of symptoms, in which case they should be left alone. At other times simply changing the posture of a recumbent patient with unilateral lung disease so that the 'good lung' is dependent improves oxygenation [28].

When reaccumulation of a symptomatic effusion occurs, further aspiration is merited; if the reaccumulation has been rapid, some form of sclerosant such as 500 mg tetracycline added to 50 mL of normal saline and 10 mL 1% lidocaine in a 60-mL syringe can be introduced intrapleurally after drainage, left overnight and any residual fluid removed the next day [29,30]. A slurry of talc in saline may be similarly used. Even with lidocaine and other analgesia, this procedure is often painful and a useful outcome not always forthcoming.

Sometimes dyspnoea may result from associated disease such as pneumonia or an exacerbation of chronic bronchitis; symptomatic relief using nebulized bronchodilators may be achieved in the latter case. The giving or withholding of antibiotics depends on the physician's assessment of whether the symptoms of infection are causing distress and whether further prolongation of life is likely to be wished for by either the patient or close relatives. It may sometimes be important to gain some extra time if, for example, a close relation is travelling from afar or if legal or other affairs need settling. At other times pneumonia may provide a welcome release to all concerned.

Frequently in terminal respiratory malignancy, treatment cannot usefully be addressed to the cause of breathlessness, which may be diffuse neoplastic spread, and remedies are directed to the symptom of dyspnoea itself. Once again a strong opioid analgesic such as morphine is required and can be used in similar doses to those already described for the relief of pain. This has the advantage of suppressing respiratory drive centrally and of decreasing anxiety and distress. It also relieves any associated chest pain, which may itself be making breathing difficult and uncomfortable. The association of chronic obstructive

airways disease with advanced malignancy is not a contraindication to the use of morphine in a patient whose life is drawing to its close and who is experiencing significant dyspnoea.

Nebulized morphine or diamorphine has been used in attempts to control dyspnoea. Reports of its efficacy in cancer have been based on uncontrolled observations and are therefore open to question [13,31,32]. As might be expected, doses used vary widely, from 5 mg morphine added to 5 mL of normal saline to as much as 50 mg diamorphine. Conflicting results have been reported when this form of treatment has been used in other patient groups, including those with dyspnoea due to severe chronic lung and heart disease [33–35]. Benzodiazepines such as diazepam starting with a small dose such as 2 mg three times daily may also help to alleviate the anxiety associated with breathlessness and are worth trying. Sublingual lorazepam 2.5–5 mg has a rapid onset of action and a short half-life, lending itself to self-administration for the management of more acute dyspnoea that may be associated with panic.

Although the provision of oxygen may have little to offer in a physiological sense, the availability of an oxygen cylinder to a person who feels the need for 'more air' may be a source of some comfort to both the patient and family. This having been said, the proper provision of morphine is likely to reduce such feelings of need for what is often a psychological crutch.

As a dying patient weakens to the extent that coughing is no longer easy, loose secretions may be heard to rattle in the larger airways during respiration. By this time the patient's conscious level may be sufficiently depressed for the sensation to go unnoticed and it may be a greater source of distress to those about the bed who have to listen to it. Repositioning of the patient may help in this respect. The traditional remedy is the atropine-like substance hyoscine hydrobromide, given at a dose of 400–600 µg every 4 h subcutaneously as necessary or infused subcutaneously at a dose of 1.2–2.4 mg over 24 h. The rationale for this is that it dries bronchial secretions and that it is less likely than atropine to cause central nervous system stimulation. The extent to which it is effective is somewhat doubtful.

## Dehydration

Whereas it is good practice to keep patients who still have a chance of recovery well hydrated and nourished when they are too ill to swallow, this line of action makes little sense in a patient who is dying; indeed there is a strong body of opinion among hospice workers that dehydration is symptomatically beneficial in terminal patients, reducing the problems of urinary incontinence and also those of loose bronchial secretions referred to in the previous section [36]. It is sensible to avoid intravenous or nasoga-

tric tube rehydration in such circumstances. Attention can instead be paid to mouth care [37], keeping the patient's mouth moistened with 2-mL aliquots of cool water by syringe or with chips of ice.

### Haemoptysis

The small haemoptyses that occur commonly in association with lung cancer are a source of anxiety to the patient and firm reassurance that they do not presage a major bleed may be all that is required. If the haemoptysis persists and is of sufficient volume to continue to cause the concern, palliative radiotherapy may very well be helpful and should be requested (see Chapter 41). In the mean time, an oral haemostatic agent such as tranexamic acid or etamsylate (ethamsylate) that tends to reduce capillary bleeding can be tried, although there are no published controlled trials to support the clinical impression that they may help in this situation. A major haemorrhage is rare, but should one occur and if the patient survives and remains conscious, an immediate intravenous injection of 5–10 mg morphine is advisable and may if necessary be followed by a similar dose of diazepam by the same route in order to reduce fear and awareness. The patient should not be left alone and blood stains on the bed linen should be covered with red or green towelling to reduce further alarm [31].

### Constipation

Constipation is an inevitable consequence of any terminal illness that is protracted and is a cause of considerable anxiety to patients unless dealt with adequately. It is best to anticipate it and treat from an early stage with laxatives, particularly in patients taking narcotics or other constipating drugs. Opioids are one of the major causes of constipation in terminal illness, tending to increase smooth muscle tone with suppression of peristalsis while also increasing sphincter tone and reducing the awareness of rectal distension. Other factors contributing to constipation are anorexia, leading to a poor intake, dehydration, inactivity and general debility. Hypercalcaemia or the use of tricyclic antidepressants may also be contributory and the possibility of spinal cord compression should not be forgotten.

It is routine to combine a stool-softening laxative with a bowel stimulant, since a single agent of either class may produce an inadequate effect. There are numerous laxatives available, the liquid preparations being referred to by some patients as 'engine oil'. It is best to become familiar with a few but to be prepared to make some adjustments according to patient preference.

Although liquid paraffin is avoided in other longer-term situations because of its propensity to cause lipoid pneumonia, it is a suitable stool softener for use in patients

with terminal conditions, a dose of 10–30 mL being taken on retiring (as combined with magnesium hydroxide in Milpar). Other agents that have stool-softening effects include the bulking agents methylcellulose, which may produce bloatedness, and lactulose, which draws water into the bowel osmotically and which has a sickly taste. Examples of bowel stimulants include senna taken in tablets or as granules 15–30 mg or bisacodyl tablets 10 mg, both taken on retiring. These preparations have effect within the following 10–12 h [38]. Another very useful alternative is the stimulant dantron (danthron), combined with a stool softener such as poloxamer (i.e. codanthramer) or the surfactant docusate (i.e. codanthrusate), both being available as capsules (two at night or up to three four times daily) or as a suspension usually to be taken at night.

If the patient remains constipated for more than 2 days and examination reveals formed stools in the rectum, then two glycerol suppositories may be used for their stimulant effect, an alternative stimulant suppository being bisacodyl 10 mg which may produce rapid results. Both of these should act within an hour or so. If examination shows the rectum to be empty then a high phosphate enema, delivered via a soft catheter inserted 20 cm into the rectum to prevent immediate expulsion, may be used. Unusually an impacted rectum requires manual evacuation combined with some form of sedation. High soap and warm water enemas are sometimes required for gross constipation that has been neglected but this is also unusual.

### Miscellaneous symptoms

#### Anorexia

Anorexia and weight loss are frequent accompaniments of advanced malignant disease. The mechanism is obscure but is likely to be multifactorial, apparently being related to the production of cytokines and to tumour type rather than size. Some predisposing factors are readily identifiable and can be dealt with appropriately.

#### Nausea

Nausea resulting from opiates may be controlled with an antiemetic such as cyclizine (50 mg) or metoclopramide (10 mg), each to be taken three times a day before meals. Haloperidol 1.5 mg at night or twice daily may also be effective. Mouth care should be meticulous. Nausea and vomiting occurring as a result of chemotherapy may be effectively prevented by a selective serotonin receptor antagonist such as ondansetron [39]. This drug, as well as granisetron and tropisetron, acts by antagonizing 5-HT<sub>3</sub> receptor-mediated activation of afferent gastrointestinal neurones before they can trigger the brainstem centres

that initiate vomiting. Prednisolone 15–30mg daily frequently improves the appetite as well as having a mild euphoriant effect but does not result in lost weight being regained [40]. An alcoholic drink before meals may also be helpful. Dexamethasone reduces vomiting due to raised intracranial pressure from brain metastases (see below).

### Dysphagia

Dysphagia may be caused by a sore or dry mouth and may be managed with regular mouth rinses. If the patient is too weak to drink, 2 mL of water can be placed in the dependent side of the mouth with a syringe every 30 min or small pieces of ice may be used for the same purpose. Nystatin suspension 200 000 units four or five times daily may be used if oral thrush is present; alternatively amphotericin lozenges may be sucked. Ketoconazole 200 mg daily for 5 days is effective in difficult cases and fluconazole 50 mg daily for 1–2 weeks may be taken if oesophageal candidiasis is suspected or confirmed by barium swallow. The latter drug may be taken long term in patients with recurrent candidiasis associated with AIDS. Oesophagitis occurring following irradiation of the mediastinum may be treated with the proprietary antacid Mucaine, which contains a local anaesthetic oxetacaine (oxethazaine), and patients can be reassured that the discomfort will resolve completely in a week or two. Extrinsic oesophageal compression may result from mediastinal lymph node metastases or direct extension of a tumour into the mediastinum, the diagnosis being confirmed by a radiographic contrast swallow examination. How this is managed depends not only on the general fitness of patients but also on their views about what they would like to be done. When symptoms are mild, a blender may produce food of the right consistency to pass the obstruction, but eventually dysphagia and regurgitation for liquids including saliva will occur and aspiration pneumonia will supervene. If the patient wishes for nothing further to be done, then heavy sedation with morphine is appropriate in order to relieve their inevitable distress. However, if the patient is sufficiently fit, a thoracic surgical opinion can be obtained concerning the insertion of a palliative oesophageal tube, or palliative radiotherapy may be considered.

### Hiccups

Hiccupping is occasionally very persistent and troublesome in a small minority of patients with thoracic cancer. There are a large number of both central and peripheral causes, including gastric distension and mediastinal invasion by tumour. Physical stimulation of the back of the pharynx with a nasal catheter, iced water or the like may stop it and is worth trying [41]. Gastric

distension may be caused by gross hepatomegaly ('squashed stomach syndrome') and patients may be helped by practical advice to take small meals followed by 10 mg metoclopramide, which promotes normal gastric emptying. Activated dimeticone (dimethicone), an antifoaming agent, may also be used as a deflatulent in such cases, 10 mL being taken after meals. Chlorpromazine may be necessary for a severe episode of hiccups but is sedating and may cause postural hypotension, particularly in the elderly. It can be tried orally at first at a dose of 10–25 mg three times daily followed by a single slow intravenous dose of 25 mg if necessary. Other treatments sometimes used include carbamazepine, nifedipine, baclofen, haloperidol, ketamine, phenytoin and, in extreme cases, intravenous lidocaine [42,43].

### Sleeplessness

Sleeplessness may be due to a readily identifiable cause such as pain, in which case appropriate analgesia can be given. Where no such cause is evident, a benzodiazepine such as temazepam 10 mg may be given. Alternatively, nitrazepam 5 mg at night may provide some anxiolytic effect the next day as this has a longer half-life. Benzodiazepines may produce confusion in elderly patients in whom clomethiazole (chlormethiazole) two capsules at night is a useful alternative.

### Symptoms due to cerebral metastases

Nausea, vomiting and pain are dealt with as outlined in earlier sections of this chapter. The decision about whether to treat more actively using steroids and/or radiotherapy must take account of the patient's general situation as well as the attitude of any close family. No particular benefit may be seen in achieving a temporary respite in a patient who is clearly in the terminal phase of the disease. In other circumstances, more active management might be considered to be in their best interests. Dexamethasone 16 mg daily for 1–2 weeks is given in order to reduce oedema around metastases. If there is no response, the drug can be rapidly tailed off. If response does occur, the dose may be reduced by 2 mg per week to a 'maintenance' dose of about 4 mg daily. Recurrent symptoms sometimes respond to an increase in the dose to its original level. A response to dexamethasone may encourage the radiotherapist to treat with palliative cranial irradiation. The opposite usually deters them from intervening.

### Epileptic seizures

Epileptic seizures are treated in conventional manner with an oral anticonvulsant such as phenytoin 150–600 mg

daily. If the parenteral route is required, diazepam 10 mg may be given intravenously over 2 min to control a persistent fit and may be repeated if necessary. An emulsified form, Diazemuls, is best used to avoid thrombophlebitis. Another option if intravenous access is difficult is to give diazepam as a rectal solution, also at a dose of 10 mg. Phenobarbital (phenobarbitone) may then be given twice daily intramuscularly if the oral route remains unavailable. When the patient is in the terminal phase, fits may be controlled by subcutaneous midazolam, given by syringe driver at a dose of 20–40 mg per 24 h. This is also suitable for very restless patients (see below) and is compatible with diamorphine.

### Confusion, restlessness and delirium

Confusion in elderly ill patients is often attributed to their inability to adapt to changed circumstances or an altered environment. Whether or not this is true, it is worth spending some time thinking through possible physical causes of confusion that might be amenable to treatment. Psychotropic drugs, including narcotic analgesics, benzodiazepines and corticosteroids, should all be suspected. Metabolic disturbances, such as uraemia, hypercalcaemia or a low blood glucose due to regular oral hypoglycaemic therapy, may be responsible for disturbances of consciousness. Confusion or agitation may also arise as a result of systemic infection, hypoxaemia or urinary retention. Sedative drugs are required if confusion cannot be settled by identification and treatment of any such cause (provided that there is no response to simple reassurance) and if it is causing distress or if it is likely to result in physical injury to the patient or anyone else. In mild cases of confusion and restlessness, haloperidol 1.5–5 mg at bedtime may be sufficient. For severe delirium, haloperidol 5–10 mg may be given subcutaneously or intravenously, being repeated hourly until the patient is settled, after which it may be continued orally if necessary. Alternatives are thioridazine 25 mg three times daily, which has to be taken orally, and chlorpromazine 50 mg intramuscularly or orally followed by 25–50 mg three times daily, the latter drug being useful if more sedation is required. Levomepromazine (methotrimeprazine) is a more heavily sedating alternative for restlessness and confusion in the terminal stage, being infused subcutaneously at a dose of 20–100 mg per 24 h. When necessary this can be combined with diamorphine in the same syringe driver. A good nursing technique is invaluable in dealing with such patients and every attempt should be made to understand and calm them. It should never be assumed that patients cannot understand what is being said in their presence and the relatives feel better if they can be given a physical explanation for the disturbance rather than be left with the impression that the doctors and nurses do not know what is going on.

## Psychological aspects

Attempts to unravel the psychology of dying are beyond the scope of this chapter. Suffice to say that the journey may be charged with many strong emotions and that appropriate action on the part of those in a position of care may work strongly to diminish the unpleasantness and to provide comfort and support in the face of suffering [44]. It is dangerous to generalize about the nature of an individual's response to the revelation that life will shortly end, but nevertheless such generalizations have been made and are widely quoted.

Kübler-Ross [45] describes five stages: first denial and isolation, then anger followed by bargaining, then depression and finally acceptance, the passage through these stages representing a gradual process of realization. In reality many reactions are encountered and they do not necessarily occur in any particular sequence. Initial incomprehension is almost invariably followed by apprehension and various mental acrobatics that are apparently performed to avoid the perception of unpleasant reality. Bargaining is said to occur if patients 'do deals' with their own conscience to behave in a certain manner in order to improve the chances of a more successful outcome. Denial may be tested by asking patients whether they have times when they feel that they may not 'beat' the illness after all. Patients are likely to experience sadness, depression or despair but may also display hopefulness and optimism and may slip in and out of these different emotions from day to day as they seek to cope with their illness. It is to be hoped that the inevitability of new circumstances is eventually accepted and that this acceptance brings with it an inner tranquillity. Certainly this peace of mind is the major objective of terminal care, as it brings comfort to the patient and is a source of strength to the family, whereas anger and resentment does the reverse. As has been previously emphasized in this chapter, it is generally thought that kindly, open and supportive discussion helps the patient to achieve acceptance.

## Organization

Most patients with terminal cancer die in hospital in the UK, and the type of terminal care that they receive is influenced not only by the training and attitudes of those who look after them but also by the other demands inevitably placed upon the staff of busy acute wards. One of the achievements of the hospice movement has been to promote discussion and to disseminate a greater understanding of the needs of the dying [46]. Whereas the acute hospital ward cannot produce the same physical environment, nevertheless it should be possible to transpose some of the organizational practices and the general ethos of the hospice or 'continuing care' unit to the management of terminal patients in any hospital. Such care depends upon

good liaison between the senior nurse on the ward, the medical team and the social worker, and time spent talking not only to the patient but also to the family and the general practitioner is in itself therapeutic. Physiotherapists and occupational therapists also play an important role in helping the patient to remain as independent as practicable. The family should be allowed to come and go as they please and should be made to feel welcome on the ward, rather than being restricted to predetermined visiting hours. Their anxieties should be listened to and an attempt should be made to deal with them in a well thought out manner. When practicable, home visits or excursions with the relations should be allowed and whenever possible the patient should be discharged with the provision of adequate social support and district nursing care. Specialized care such as that given by Macmillan nurses may be made available and provision should be made for readmission if the need arises.

The anxieties of patients should be appreciated; many fear separation from their family and home and are happier in their own surroundings if this can be arranged. A fear of dependence on others is also common and this may be alleviated by avoiding an impatient or patronizing attitude, so that care is delivered as though it was a privilege rather than a chore. Concerns about how the surviving relatives will cope may be prominent and if voiced are best dealt with in a practical manner, sometimes with the help of a sympathetic social worker, hospital chaplain or other minister of religion. A study that asked patients from whom they most wanted emotional support and from whom they most got it indicated that their first choice was their doctor and that senior doctors were perceived as providing more emotional support than junior colleagues, leading to the conclusion that this form of comfort stemmed from what was thought to be the provision of accurate and authoritative information [47,48].

# MEDICOLEGAL ASPECTS OF LUNG DISEASE

ANTHONY SEATON

At its simplest, the law exists to protect citizens, their property and the environment within which they exist from harm due to the actions or omissions of others. Doctors may become involved in legal processes in their role as citizen, as when they are sued by an aggrieved patient or, fortunately rarely, accused of a criminal offence such as unlawful killing, or in their role as medical expert when asked to give evidence about the causation and consequences of disease. This chapter is concerned with the latter role, relating particularly to lung disease.

The great majority of cases in which a medical expert is likely to be involved occur under the civil, as opposed to the criminal, law. The difference is important with respect to the legal definition of proof, a matter not always appreciated by doctors. In criminal law, in which a crime is alleged to have been committed, it is necessary for the prosecution to prove a case 'beyond reasonable doubt'. This form of proof is similar to that with which we are familiar in our clinical role, in which we pursue the investigation of a patient until fairly certain that we know the diagnosis. In contrast, in civil proceedings it is only necessary for the litigant (sometimes referred to as the plaintiff or pursuer) to prove the case 'on the balance of probabilities', i.e. greater than 50% likelihood or more likely than not. This test applies to all matters in contention, such as the presence of a particular disease, the likelihood of something having caused it and whether appropriate measures were taken to prevent it. In most jurisdictions, civil cases are argued before a judge, both parties being represented by lawyers who examine their own witnesses and cross-examine those called on behalf of the other side. The judge arrives at a verdict and decides the amount of the award in damages. In contrast, in the USA all cases are argued before a jury, which is responsible not only for the verdict but also for assessing the amount of the award. In general the award of damages takes account of all financial losses, both actual and likely future ones, in terms of earnings, expenses and so on, and of pain and suffering. Again, in the USA an additional sum is often added by the

jury, so-called punitive damages, often adding considerably to the award.

A further difference between the USA and most other jurisdictions is the method of obtaining the services of a lawyer. In most countries, the transaction involves a fee for service, usually calculated on the basis of guidelines issued by the relevant professional body. This means that the costs of litigation are considerable and, as has been found by many who have sued unsuccessfully for libel, ruinous. The costs may be recovered if the action is successful, at the discretion of the judge, but if the litigation is unsuccessful they fall upon the litigant. Thus only the very wealthy can usually afford to embark on legal action unsupported by some other agency. In the USA this problem has been overcome by the introduction of a system of contingency fees, lawyers agreeing to act for a client on a speculative basis with an agreement that they will pay the costs if unsuccessful but will take a percentage of the damages if successful. The introduction of a similar system is likely in the UK, and has already been introduced by some law firms. From the experience in the USA it seems to be associated with inflationary pressures on court settlements and acts as a stimulus to an ambulance-chasing form of legal behaviour. However, it does ensure that anyone with a reasonable case can obtain legal representation. In the UK, most injured workers manage at present to obtain support from their trade union, a powerful reason for being a member of one, or from the state through legal aid. Legal aid is means-tested and is likely to be available to fewer people in future as part of an effort to control government expenditure.

## Compensation

### No-fault benefits

It is not uncommon for a doctor to be asked by a patient if he or she is entitled to compensation for some work-related lung disease. In these circumstances, it is wise to advise the patient to consult a lawyer, preferably through

the trade union. If the patient is not a member, limited advice may be obtained from the Citizens' Advice Bureaux or similar organizations. However, there is some useful advice that a doctor can give. Most importantly, doctors should be aware of the system of no-fault benefits available in their country or state. In the UK there is a state-funded system of industrial injuries benefits available to all employed people (but not self-employed, who have to make their own insurance arrangements) who suffer an injury or illness as a result of their work, funded from the social security budget. While any work-caused injury is potentially eligible for compensation, benefits for illnesses are only available if the illness is prescribed, i.e. on a list agreed by Parliament. This list is updated regularly as a result of the recommendations of an independent committee of experts, the Industrial Injuries Advisory Council, who base their advice on the medical, mainly epidemiological, evidence relating diseases to work. The lung diseases currently prescribed on this list are shown in Table 61.1.

Before advising a patient to seek industrial injuries benefit, the doctor should ensure first that the patient is or was employed as opposed to self-employed. It is also the case that this system of compensation is not available to

members of the armed services, who may however be able to obtain war pensions instead. Secondly, it is necessary to be reasonably sure that the disease was caused, and not simply made worse, by work. Thirdly, the illness must be one that is on the list of prescribed diseases and the patient must have been working in a trade in which a relevant exposure is likely to have occurred. Alternatively, if the illness occurred as a consequence of an accidental exposure, say to a toxic gas or fume, benefits may be claimable for an industrial injury rather than for a prescribed disease. If these conditions are fulfilled, the patient should be told that it is worth applying for benefits and an explanation of the process given. Application must be made by the patient to the local branch of the Department of Social Security (DSS), where a form needs to be completed, indicating the disease being claimed for and the work that the patient has been doing. There then follows an interview with an insurance officer, whose job is simply to ensure that the applicant has indeed been employed and is eligible for benefits if the prescribed disease is present. The papers are then sent to the regional panel of DSS doctors specializing in respiratory diseases, whose role is to determine, on the balance of probabilities, whether the patient has the prescribed disease and to determine the extent of disablement ascribable to it. This determination is expressed in terms of loss of faculty, i.e. loss of the functional abilities of a healthy person of the same age and sex, account being taken of the employability of the individual as a result of the illness. A percentage figure for loss of faculty is arrived at and this is usually applied by the insurance officer to calculate the benefit payments. A sum for 100% disability is agreed by Parliament each year. In some circumstances, a lump sum payment may be made to the claimant, but more usually an annual pension is awarded and this may be adjusted after further medical assessments in the light of improvement or deterioration in the patient's condition. Such reviews usually take place every 2 years. If a patient is unsuccessful in claiming benefit, there is a mechanism for appeal to a Medical Appeals Tribunal, chaired by a lawyer and including doctors with special experience of lung disease.

This system of state benefits was introduced at a time when injured workers were effectively unable, because of the costs of litigation and lack of a system of social security, to obtain any compensation and were often rendered indigent. It remains in force now despite a comprehensive system of sickness benefits available to those unable to work for whatever cause, and therefore provides people injured at work with benefits additional to those available to someone injured, say, in a domestic accident or suffering from some illness as a result of ill-fortune. It may therefore be regarded as something of an anomaly, and in recent years there has been a progressive erosion of the value of the benefits payable. At one time it served to limit the numbers of people seeking redress through the courts, but

**Table 61.1** Prescribed occupational lung diseases in the UK.

Disease	Prescribed occupation
Anthrax	Contact with animals or their products
Tuberculosis	Medical or laboratory contact
Extrinsic allergic alveolitis	Agriculture, malt work, mushroom growing, bird handling, bagasse handling
Asthma	Exposure to a sensitizing agent
Byssinosis	Contact with cotton or flax dust
Various poisonings	Exposure to mercury, cadmium, nickel carbonyl, beryllium, nitrogen oxides
Pneumoconiosis	Mining, quarrying, ceramics, foundry work, asbestos handling, etc.
Mesothelioma	Asbestos handling
Lung cancer	Nickel refining, asbestos handling (if asbestosis or diffuse pleural fibrosis is also present), and in the presence of silicosis
Nasal cancer	Nickel refining, woodwork, shoe manufacture
Bilateral pleural fibrosis	Asbestos handling

For full details, see *Notes on the Diagnosis of Occupational Disease* (1979) HMSO, London; and leaflets published by the Department of Social Security: NI 3 (pneumoconiosis) and NI 238 (asthma).

more recently an award of benefits is often taken as an indication that a claim in civil law is likely to be successful; this is far from always the case, since in civil litigation it is necessary not only to show that the disease is present and was caused by the work but also to prove that it occurred as a consequence of the employer's negligence. If a patient is successful in obtaining damages in a civil case, any state benefits paid in respect of the illness are repayable.

### Civil litigation

When patients wish to sue their employer, the main role of the doctor is in advising them whether they have a work-related disease or not, and it is then up to patients to seek advice from a lawyer. The date at which this advice is given should be recorded, since in most jurisdictions there is a limited time available from the moment the patient became aware that the illness was caused by work for the lawyer to lodge a claim against the employer(s). This so-called time bar sometimes becomes an issue when a patient only decides to see a lawyer after hearing of a successful claim by a colleague, most commonly for a relatively trivial condition such as pleural plaques.

The process of civil litigation involves the issue of a writ, or a statement that the litigant is suing the employer for a stated sum in compensation for suffering and loss incurred as a result of illness caused by the negligence of the person sued. The negligence is defined in terms of the defender's failure to comply with the law as it obtained at the time the injury occurred. This is then answered by the lawyers acting for the defender, who generally enter a robust denial of any negligence or of any knowledge that the litigant has indeed suffered any injury. These documents appear to represent irreconcilable views but can be taken to be opening moves in a prolonged game in which evidence is obtained and challenged, leading in most cases to an agreement between the parties prior to appearing in court. Occasionally, however, the case actually reaches the courts and is argued before a judge, witnesses being examined and cross-examined by advocates. This outcome should always be anticipated by any doctor writing a report for a lawyer.

Lawyers, like doctors, specialize and some firms are particularly effective in the area of work-related illness. The good lawyer seeks the opinion of a doctor recognized as an expert in the field of lung disease as to what the illness is, what is likely to have been the cause, to what extent the patient is disabled and the likely prognosis. In general, advice is not sought from a chest physician as to whether or not the person being sued was negligent, since this is a legal matter. However, the lawyer may require advice about the state of medical knowledge at the time the injury is alleged to have occurred in order to determine whether the defender could reasonably have foreseen the consequences of the alleged negligence. Both parties to the

litigation seek advice independently from experts, both in respect of diagnosis and disability and often also in relation to conditions in the workplace. Having obtained such evidence as they require, they usually consult with a trial lawyer (barrister in England, advocate in Scotland) and decide how to proceed. The costs of a court hearing are considerable, and in most cases settlement can be arrived at by a process of discussion (or a game of cat-and-mouse) between opposing lawyers, the decision often being reached shortly before the hearing and indeed sometimes on the first day. This settlement is usually reached on the basis of a payment, including costs, by the defender to the litigant without accepting responsibility for the injury. If after such an offer is made and refused the case proceeds to trial and the litigant is subsequently awarded a smaller sum in damages than that offered, the responsibility for costs of the action may fall on the litigant. There is thus a good incentive to accept a reasonable offer.

If the case proceeds to trial, the lawyers state their positions before the judge and call witnesses. All witnesses, whether giving evidence about conditions in the workplace at the relevant time or an expert opinion, are led through their evidence by the lawyer for whom they are acting and then cross-examined by the lawyer for the other side, whose job it is to discredit them. At this point, every word and opinion written in a report may be subject to the most detailed inquisition. Any papers quoted in support of statements by an expert may be dissected, and the opinions put forward by one doctor are likely to be challenged by those of another. The whole process requires not just a cool head but also an unshakeable ability to justify all one says and all one has already committed to paper. It is never an enjoyable experience and can be likened to an anatomy viva prolonged, sometimes, for a day or two! This possible outcome should be borne in mind by anyone writing a report for a lawyer. With the agreement of the judge, witnesses may be recalled to deal with matters brought up in subsequent evidence and some trial lawyers may ask experts to assist them through the course of the trial with informal medical advice. Once the evidence has been heard, the lawyers summarize their cases and the judge eventually delivers a decision and, if finding for the plaintiff, decides on an appropriate sum in damages and costs.

The system in the USA differs in several ways. The trial lawyer may often conduct both the investigative and trial parts of the action, and is likely to wish to maximize the chances of success by giving advice to the expert on such matters as how to address a jury, how best to present a case and so on. Witnesses are often required to make a deposition before the case comes to court; lawyers call this 'being deposed' and it involves being questioned for a prolonged period by the lawyer from the other side in order to find out what evidence will be given and just how knowledgeable the witness really is. If the case comes to trial it is

argued before a jury and all sorts of stratagems are used to convince the jurors of a witness's veracity and expertise. The process is undoubtedly less gentlemanly than the British version, and clearly the lawyers for the litigant, being on a contingency fee, have a lot more at stake than just professional pride. In both systems, however, when a case comes to court the arguments are usually finely balanced and the most important factors in determining the outcome are the expertise and skill of the advocate and the competence of the expert witnesses.

### **Role of the doctor as expert**

From what has been said above, a doctor should not agree to write an expert medical opinion unless he or she has a particular knowledge of the subject and should confine any opinions to those pertaining to these areas of expertise. There may be a temptation to overstep these limits in support, perhaps, of one's patient but this should be resisted for fear of having to justify them in the witness box in the face of conflicting evidence from a real expert and from the literature. A doctor is approached by lawyers from one or other side, and here again there is a temptation to slant one's evidence in favour of that side. While this is understandable and may indeed be encouraged by some lawyers, it is unwise since it leads to difficulties in justifying the opinion under cross-examination and possible loss of credibility as an expert. An expert should give as honest and impartial advice as possible and it is for the lawyers to act as advocates. It can be argued that good lawyers want to know the truth, even if it does not support their case, since this helps to decide on settlement and thus minimize costs. This does not mean that an expert should not point out possible defences or weaknesses in the other side's case, where such matters fall within his or her field of expertise. In an ideal world, the opinions of experts about an individual patient should differ little, and this in fact is frequently the case with respect to disease and its causation. There is often greater scope for disagreement with respect to prognosis, though even here agreement is usually possible by compromise. Exchange of medical reports prior to trial, in the expectation of being able to resolve relatively small differences, is becoming more common in British actions and is a desirable tendency.

### **Expert medical report**

A report is written in response to a letter requesting advice from a lawyer, and that letter should ask the questions that the lawyer wishes answered. In general there are four: what disease does the client suffer from, is it likely that the illness was caused by the client's work, how disabled is the client and what is the prognosis? If the doctor is an expert in occupational medicine, the lawyer may

in addition wish to know whether the precautions taken to prevent disease were reasonable in the light of knowledge at the time in question. The letter may ask the expert to examine the patient or it may simply request an opinion on various records, statements by others and radiographs.

The format of the report is of course a matter for the individual doctor, although it is sensible to have one's personal style and stick to it in order to avoid neglecting any important matters. It is usual to head it with a note of the case and a statement of what was done and when. If the doctor has not previously worked for the lawyer requesting advice, it may be helpful to state one's qualifications, both formal and in respect of one's expertise in the case at hand, and it is usual to provide the lawyer with a short curriculum vitae. Clinical and research experience with respect to the alleged condition are relevant, as are any personal publications on the subject. However, it is worth noting that any such publications can appear in court at a later stage if they appear to contradict any part of the evidence given in the report or orally in court, and may result in dramatic loss of credibility! The author has come across a report written by an expert denying the existence of a condition that he himself had described some two decades previously, an act of carelessness that destroyed his case.

The report should then detail the findings from the history and examination of the litigant, from careful reading of any written material provided or from both. It is usually sensible to seek corroboration of the clinical history, which may be imperfect on account of forgetfulness or deliberate deceit, from hospital and general practice notes. The lawyer should be asked to obtain these prior to seeing the client if at all possible and they should normally be reviewed prior to writing a definitive report. Particular care should be taken over the occupational history, since this is crucial to determining if work was likely to have been responsible for the condition. If the illness is thought to have been caused by an acute exposure to toxic gas, full details of the episode are necessary together with their temporal relationship to the onset of symptoms. All available evidence as to what gases or fumes were involved, where the exposure took place and for how long, and what were the likely concentrations should be considered. Lawyers are often able to provide data sheets and witness statements in such circumstances and should be asked to obtain them if they are not available. It is of course essential to form an opinion on the health of the client prior to the accident and how it has changed as a result. In the case of illness thought to be due to longer exposure, as in the case of mineral dust diseases, a lifetime occupational history is essential, again making particular note of possible levels and duration of exposure to harmful substances. This information on likely exposures is often disputed in actions that reach the court, and

it is crucial to convince oneself that the individual's history is consistent with the disease that is present.

It is usual as part of the process of examination to include certain tests, depending on what has been done before. A chest radiograph is clearly essential in many cases, as are lung function tests. However, in the case of occupational asthma it is useful to remember that the legal test of proof is on the balance of probabilities, and such tests as serial peak flow rates and challenge with suspected antigen are rarely necessary. Indeed, challenge testing has potential hazards and should only be considered as part of a clinical rather than medicolegal investigation.

Having recorded the findings, it is usual to provide a commentary written in non-technical language. This is conveniently set out under headings corresponding to the questions asked by the lawyer. Thus, the first section might be headed 'What does the client suffer from?', the next 'What are the likely causes?', then 'How disabled is the client?' and finally 'What is the prognosis?'

In assessing disablement, a particular problem commonly arises when the litigant has two or more conditions. A sensible balanced judgement should be made as to which are the main contributors to disability. For example, it is not uncommon to see people whose disability has been attributed to pleural fibrosis when they have normal lung function but clear evidence of ischaemic heart disease. The author has seen patients with breathlessness due not only to this condition but also undiagnosed atrial septal defect and motoneurone disease, in all of whom an expert had confidently attributed the symptom to pleural disease. The patient with atrial septal defect was actually cured of his symptom as a result of entering the process of litigation, having missed this benefit from the normal medical process.

In discussing disablement, it is important to differentiate between impairment, disability and handicap. An abnormality of lung function is a measure of *impairment*, and is convincing evidence of lung disease if the tests have been done carefully and reliably. In this respect it is always wise to check the original traces if the tests were not done personally. However, it does not of itself provide a measure of *disability*, which takes account of the expected activity levels of a person of the same age and sex. A person with abnormal lung function may be free of disability because the impairment does not interfere with normal activities, while someone with normal lung function may be disabled because of psychological breathlessness due to anxiety about, for example, a spurious diagnosis. The level of disability is assessed from the history and its likely cause is judged by considering the results of the lung function tests. *Handicap* is a measure of the amount to which individuals are prevented from pursuing their normal lives and therefore takes account of their work. Thus someone with occupational asthma due

to spraying isocyanate paints may no longer show any impairment of function or disability but may be severely handicapped in the job market because of an inability to work in the paint-spraying trades. All these points and the subtle distinctions between them need to be considered in writing that part of the report that answers questions about level of disability.

The question of prognosis is often critical if the disease is proved, since it is an important factor in determining the level of damages. If available, serial lung function tests and radiographs from the client's records are invaluable in determining prognosis and should never be ignored. It is common for doctors to take unduly optimistic or pessimistic views, depending on which side they are appearing for. This is unwise, since cases often take years to come to court and it can be embarrassing to see someone hale and hearty whom one confidently predicted would be on his last legs, or vice versa. If possible, one's prognosis should be based on epidemiological and clinical studies in the literature as well as one's own experience. The prognosis should cover not only the disease or diseases in question but also any other disease that may follow in the future as a complication of the present illness or its causes. This is particularly relevant with respect to asbestos, where damages paid to people with benign pleural plaques takes account of the future possibilities of developing mesothelioma.

This section discussing the findings and their implications should then be followed by a succinctly expressed opinion that the writer would have no difficulty defending under cross-examination. There is the likelihood of challenge in all these parts of the report; the diagnosis and the cause are usually contested and there is plenty of scope for debate on level of disability and prognosis. This opinion should state in simple terms the views arrived at on each of these points. If there is insufficient evidence on which to arrive at a conclusion, even on the balance of probabilities, this should be stated and a recommendation for further medical or legal investigation should be made. In these circumstances it is usual to offer to write a supplementary report when the further information has been produced.

### Appearing in court

Receipt of a carefully argued report should assist a lawyer to decide whether the case is worth pursuing, abandoning or settling out of court. Whichever side the report is written for, a clear, honest and straightforward opinion is of much greater value than an equivocal one, even if it does not support the side who have requested it. If it is decided to pursue the case, nothing is likely to be heard for a year or two as various legal procedures are followed and further evidence obtained. The most likely outcome is agreement to settle, usually just before the hearing. Before

this, it is usual for the lawyer to have a conference, and if the medical evidence is in dispute the doctors who have written reports are usually asked to attend. This helps the trial lawyer to prepare the case and courtroom tactics and is an opportunity to test the strength of the expert evidence. Thereafter the expert is summoned to court, and it is usually possible to negotiate a time within fairly tight limits. Evidence is given under oath and commences with a benign examination by the lawyer on the same side. It is usual to be asked to describe one's qualifications and position and the lawyer also asks some questions designed to demonstrate to the judge one's unique and unrivalled expertise, in comparison to the experts on the other side. The written report is likely to be discussed and the opinions expressed therein reiterated. The fun then begins with the cross-examination, when the other side's lawyer tries to show, albeit politely at first, that one's expertise is insubstantial and that the report was written on the basis of a poor appreciation of the facts of the case; in short, that one's opinion is of no value compared to that of the other experts. In the course of this there may be detailed discussion of papers from the literature that have been included as evidence and which have to be interpreted for the judge. It is as well to have read these papers carefully beforehand. After the cross-examination, the original lawyer has a chance to re-examine the expert in order to correct any false impression that may have been given and to direct the judge's attention back to the essentials of one's evidence.

All one's evidence in British civil courts is addressed to the judge, who should be spoken to with due deference and addressed by the proper title, usually 'my lord/lady'. The judge often intervenes with questions and requests for clarification or explanation. In courts in the USA, one gives one's evidence to the jurors, and this should be given at an appropriate level of comprehensibility. Again, the judge also intervenes from time to time for clarification. It is unusual to be asked to attend court throughout a hearing, although occasionally a lawyer might value an expert's comments on the evidence of other witnesses, and wish to hold conferences during the course of the trial. Generally, however, it is possible to arrange to attend simply to give evidence and then disappear.

## Trends in litigation

The respiratory disease medicolegal industry in the USA has been built on asbestos, though there is substantial activity also with respect to coal, quartz and chronic airflow obstruction. In the UK, there has been and continues to be much asbestos litigation, most concerned with benign pleural disease and mesothelioma. However, occupational asthma and acute lung disease due to inhalation of toxic substances are common conditions, as

discussed in Chapters 34, 36 and 54, and there is a rising trend of litigation in these areas. Chronic airflow obstruction in groups of workers where epidemiological evidence suggests an increased risk, such as coal-miners and welders, has also been an increasing cause of litigation. Changes in the value of, and access to, disability benefits and reduction in regulation of industry as part of British government policy is likely to lead to a rising trend both of litigation and of the diseases that provoke it.

## Postscript

Books such as this are not written overnight and, since this chapter was originally drafted, new Civil Procedure Rules have been introduced for actions in the English and Welsh (but not Scottish) courts. These respond to a report by Lord Justice Woolf which took a refreshing look at the waste of public money on much of this litigation. The Rules are happily consistent with the advice given above and should eliminate much of the unsatisfactory behaviour of doctors and other self-styled 'experts' taking on the role of advocate. They should also reduce the likelihood of busy and expensive doctors having to appear in court. With respect to experts, the Rules indicate that:

- 1 Evidence should be confined to that which is reasonably required to resolve the proceedings.
  - 2 It is the duty of an expert to *help the court*.
  - 3 This duty overrides any obligation to the person from whom the expert has received instruction.
- The court will approve the appointment of experts and may direct that only one such be appointed, to be agreed by the two parties. The Rules set down the form and content of the report, as follows. It must:
- 1 be addressed to the court;
  - 2 give details of the qualifications of the expert;
  - 3 give details of the literature relied upon;
  - 4 state who carried out any tests and give that person's qualifications;
  - 5 where there is a range of opinion, summarize that range and give reasons for the expert's own opinion;
  - 6 contain a summary of the conclusions reached;
  - 7 contain a statement that the expert understands his/her duty to the court;
  - 8 contain a statement setting out the written and oral instructions received; and
  - 9 state as follows: 'I believe the facts I have stated in this report are true and that the opinions I have expressed are correct'.

This last statement may form an appropriate note on which to end this book. It is our hope that the facts stated herein mostly turn out to be true and that the opinions which we have expressed are sensible and ultimately benefit our patients.

 complications 708  
 controlled 1497, 1498  
 end-inspiratory pause 1496  
 endotracheal tube 1502–4  
 expiration  
 control 1497  
 initiation 1496  
 termination 1495–6  
 expiratory retard 1497  
 factors influencing institution 702  
 gas exchange during 1501–2  
 general management of patients 706–7  
 high-frequency 705, 1499–500  
 jet 713, 784  
 oscillatory 713  
 indications 704, 1509–911  
 infective polyneuropathy 711  
 inspiration  
 control 1495–7  
 initiation (ventilatory triggering) 1495–6  
 termination 1496  
 inspiratory–expiratory ratio, frequency and times 1496–7  
 inspiratory limitation 1496  
 inspiratory pressure and flow waveforms 1496  
 inspiratory pressure support 1499, 1499  
 intermittent mandatory 704–5, 1499
